**ABSTRACT:** We study the statistics of the metric on Kähler moduli space in compactifications of string theory on Calabi-Yau hypersurfaces in toric varieties. We find striking hierarchies in the eigenvalues of the metric and of the Riemann curvature contribution to the Hessian matrix: both spectra display heavy tails. The curvature contribution to the Hessian is non-positive, suggesting a reduced probability of metastability compared to cases in which the derivatives of the Kähler potential are uncorrelated. To facilitate our analysis, we have developed a novel triangulation algorithm that allows efficient study of hypersurfaces with  $h^{1,1}$  as large as 25, which is difficult using algorithms internal to packages such as Sage. Our results serve as input for statistical studies of the vacuum structure in flux compactifications, and of the distribution of axion decay constants in string theory.

# 1 Introduction

The vacuum structure of compactifications of string theory to four dimensions is extremely complex, and direct enumeration of all vacua appears impossible. Moreover, it is plausible that the number of vacua of string theory that are consistent with all present observations vastly exceeds the number of measurements of fundamental parameters that could be performed in the future. In this situation it is impractical, and for many purposes misguided, to pursue individual vacua of string theory as candidate models of the observed universe. A more fruitful course is to determine the characteristic properties of classes of vacua, and make statistical predictions [1].

An idealized enumerative approach to vacuum statistics would begin with discrete data, including the compactification topology and a specification of quantized fluxes, and compute the full four-dimensional low-energy effective action as a function of these integer inputs. One could then study the statistics of physical observables of interest in the ensemble of effective actions resulting from all possible choices of discrete data. However, despite extensive efforts to understand the statistics of string vacua (for reviews with references, see [2–4]), the present reality falls short of this ideal. In particular, quantum corrections to the effective action are poorly understood, and many of the most incisive results concern the distribution of supersymmetric Minkowski vacua of a subsector of the theory, in the classical approximation. For example, the elegant result of [5] in type IIB flux vacua describes an index approximating the distribution of configurations for which the classical F-flatness conditions for the complex structure moduli hold. The Kähler moduli, which can parameterize important instabilities, are not included.

A central idea advanced in [1, 5–7] is that a reasonable approximation to the true distribution of string vacua can be obtained by determining the statistics of vacua in an associated ensemble of  $\mathcal{N} = 1$  supergravity theories that are random in an appropriate sense. The expectation is that the Wilson coefficients of operators in the associated ensemble, when viewed as stochastic variables, will closely follow the distribution of the true Wilson coefficients that would be obtained if one could produce and study a large ensemble of genuine string vacua. Ideally, this expectation can be checked and refined by comparison to small ensembles of string vacua in computable special cases.

To specify an appropriate ensemble of random supergravity theories, one must provide an ensemble of superpotentials  $W$ , each of which is a holomorphic section of a nontrivial holomorphic line bundle over the moduli space  $\mathcal{M}$  parameterized by the scalar fields  $\phi^a$  of the theory, as well as a corresponding ensemble of Kähler potentials, which in local coordinates are real analytic functions of the  $\phi^a$  and their conjugates  $\bar{\phi}^{\bar{a}}$ . In the simple special case of supersymmetric Minkowski solutions, the vacua are determined by holomorphic equations of the form

$$\frac{\partial W}{\partial \phi^a} = 0, \tag{1.1}$$

with no dependence on the Kähler potential. The task of computing the distribution of supersymmetric Minkowski vacua therefore requires only the specification of statistical properties of superpotentials, and some significant mathematical results are applicable to

this problem: there exists a precise notion of a random holomorphic section of a random holomorphic line bundle in this context [8].

Unfortunately, knowledge of the superpotential alone is insufficient for studying supersymmetric vacua with nonvanishing cosmological constant, or non-supersymmetric vacua of any type: one must also specify the Kähler potential. Rather little is known about what one could reasonably call a *random Kähler potential*, or a *random Kähler metric*, especially for  $\dim_{\mathbb{C}} \mathcal{M} > 1$ , which is the case of primary interest (though see [9–11] for recent progress). Because possible Kähler potentials are poorly characterized, it appears difficult to give a precise definition of a *random supergravity theory*, and thereby to create a well-defined ensemble of effective theories whose statistics could accurately model the statistics of non-supersymmetric solutions of string theory.

In this work we begin to address this question, by exploring the characteristics of Kähler metrics in a well-motivated ensemble of effective theories. Specifically, we study the Kähler moduli spaces of compactifications of string theory on Calabi-Yau hypersurfaces in toric varieties, considering in detail O3/O7 orientifolds of type IIB.<sup>1</sup> A primary goal is to understand the extent to which the resulting ensemble of Kähler metrics can be viewed as an ensemble of random matrices without “special” properties. Said differently, our null hypothesis — assumed implicitly or explicitly in earlier works such as [1, 5–7, 16] — is that the various covariant derivatives of the Kähler potential at a fixed point in field space are tensors whose components are statistically independent and identically distributed (i.i.d.). For brevity, we will say that the Kähler potential is an *i.i.d. function*.<sup>2</sup> This is a rather strong assumption, which few would argue describes the actual set of Kähler potentials arising in Calabi-Yau compactifications, but it has been used in the past for want of a ready alternative. By exploring an ensemble of explicit Calabi-Yau compactifications gathered from the Kreuzer-Skarke database [18] we will be able to reject the null hypothesis in the case of the Kähler moduli sector, exposing some of the underlying structure of the metrics on Calabi-Yau moduli spaces.<sup>3</sup> This is a step toward specifying the ensemble of possible non-holomorphic data along the lines that possible superpotentials were characterized in [8].

More specifically, our null hypothesis is that the curvature contribution to the Hessian matrix,

$$(\mathcal{H}_R)_{a\bar{b}} := -e^{\mathcal{K}} R_{a\bar{b}c\bar{d}} \bar{F}^c F^{\bar{d}}, \quad (1.2)$$

can be modeled, as proposed in [16], as the sum of a Wigner matrix and a Wishart matrix,

$$(\mathcal{H}_R)_{a\bar{b}} \approx (\mathcal{H}_R^{\text{WW}})_{a\bar{b}} := \underbrace{\mathcal{K}_{ac} {}^e \mathcal{K}_{\bar{b}\bar{d}e} \bar{F}^c F^{\bar{d}}}_{\text{Wishart}} - \underbrace{\mathcal{K}_{a\bar{b}c\bar{d}} \bar{F}^c F^{\bar{d}}}_{\text{Wigner}}. \quad (1.3)$$

where  $\mathcal{K}_{\bar{b}\bar{d}e}$  and  $\mathcal{K}_{a\bar{b}c\bar{d}}$  denote derivatives of the Kähler potential  $\mathcal{K}$ , and  $F_a$  is the F-term.

<sup>1</sup>While this class provides a large number of examples, it is by no means exhaustive. For instance, see [12–15] where the properties of more general Calabi-Yau manifolds are considered.

<sup>2</sup>We use the term “i.i.d. function” to avoid confusion with other notions of random functions, which can entail correlations among derivatives. See [17] for an analysis of Gaussian random functions in a related context.

<sup>3</sup>Kähler potential data of an ensemble of Calabi-Yau manifolds gathered from the Kreuzer-Skarke database were also used in [19] to explore the prevalence of the Large Volume Scenario vacua of [20].

We find compelling evidence against (1.3). For Calabi-Yau hypersurfaces in toric varieties, the eigenvalue distributions of  $\mathcal{H}_R$  constructed from explicit Kähler potential data have *much longer tails* than predicted by (1.3). The spectra we obtain are very leptokurtic, with a sharp peak and heavy tails. We obtain a related result for the Kähler metrics themselves: the eigenvalue spectra of the metrics on Kähler moduli spaces exhibit large hierarchies and heavy tails, at least in the case of O3/O7 orientifolds that we study directly.

We then argue that for Calabi-Yau hypersurfaces in toric varieties, the structure of the Kähler metric on  $\mathcal{M}$  leads to distinctive changes in a basic statistical observable, the probability of metastability, in comparison to the probability resulting from the null hypothesis for the Kähler metric. Specifically, significant correlations originating in the geometry of the moduli space ensure that the covariant derivatives of  $\mathcal{K}$  are *not* all independent, and we argue that, in the case of O3/O7 projections of type IIB, these correlations turn out to make the probability of metastability lower in the actual effective theory than it is in an effective theory where the Kähler potential is an i.i.d. function. As a result, even though our analysis establishes that one of the working assumptions of [16], namely (1.3), must be modified substantially to reflect the Kähler moduli sector of actual Calabi-Yau compactifications,<sup>4</sup> the qualitative conclusion of [16], which is that instabilities are extremely prevalent at generic points in the moduli space, appears to be *strengthened* by our findings, at least in this corner of the landscape.

The presence of lengthy tails in the distribution of eigenvalues of the metric also has significant consequences for model-building with axions in string theory, because axion decay constants  $f_a$  are given by (the square roots of) eigenvalues of the Kähler metric. While individual axion decay constants have been computed in special cases [21, 22], trends in models with multiple axions have not previously been characterized. Our finding that the largest eigenvalues are hierarchically larger than the median eigenvalues implies qualitative changes in scenarios for axion inflation in string theory.

This paper is organized as follows. In section 2 we review the application of random matrix theory to the supergravity Hessian, and then discuss how to include deterministic data on Kähler metrics in this approach. In section 3 we review the Kähler moduli space of O3/O7 orientifolds of Calabi-Yau manifolds and prove an important negativity result for the curvature Hessian  $\mathcal{H}_R$  (1.2). In section 4 we describe our method for generating an ensemble of moduli space metrics and curvature Hessians. In section 5, we present our primary results, demonstrating the existence of hierarchies and heavy tails in the spectra of the metric and  $\mathcal{H}_R$ . We also elucidate the source of the heavy tails in  $\mathcal{H}_R$  and discuss potential implications for metastability. In section 6 we discuss alternatives to the i.i.d. model for the curvature Hessian, including a qualitatively successful approach in which the metric on moduli space is modeled as a Bergman metric. In section 7, we consider the consequences of the eigenvalue distribution of the Kähler metric for the spectra of axion decay constants. Our conclusions appear in section 8. Appendix A contains an abbreviated review of toric varieties and their Calabi-Yau hypersurfaces, which are the focus of our study. Finally, in appendix B we present an efficient algorithm to triangulate the polytopes encoding the toric variety data.

---

<sup>4</sup>The superpotential is manifestly not an i.i.d. function of the Kähler moduli, cf. [16].

## 2 Random Kähler metrics and random supergravities

In this section, we review the Hessian matrix in four-dimensional supergravity (section 2.1) and recall how it can be modeled using the tools of random matrix theory, following [7, 16] (section 2.2).

### 2.1 The supergravity Hessian

A four-dimensional  $\mathcal{N} = 1$  supergravity theory with  $N$  chiral supermultiplets containing complex scalar fields  $\phi^a$  is specified by a real Kähler potential  $\mathcal{K}(\phi^a, \bar{\phi}^{\bar{b}})$  and a holomorphic superpotential  $W(\phi^a)$ . The bosonic action is

$$S = \int d^4x \sqrt{-g} \left\{ \frac{1}{2} R - \mathcal{K}_{a\bar{b}} \partial_\mu \phi^a \partial^\mu \bar{\phi}^{\bar{b}} - V \right\}, \quad (2.1)$$

in which we have set the reduced Planck mass to unity,  $R$  is the Ricci scalar associated with the four-dimensional spacetime metric  $g_{\mu\nu}$ , and the F-term potential is

$$V = e^{\mathcal{K}} \left\{ F_a \bar{F}^a - 3|W|^2 \right\}, \quad (2.2)$$

where  $F_a$  is the Kähler-covariant derivative of the superpotential,

$$F_a = \partial_a W + \mathcal{K}_a W. \quad (2.3)$$

Indices are raised and lowered with the Kähler metric  $\mathcal{K}_{a\bar{b}}$ . The action (2.1) is invariant under the Kähler transformations  $\mathcal{K} \rightarrow \mathcal{K} + f + \bar{f}$ ,  $W \rightarrow e^{-f} W$ , where  $f$  is a holomorphic function of the scalar fields. The Hessian matrix is constructed from second derivatives of the potential

$$\mathcal{H} = \begin{pmatrix} V_{a\bar{b}} & V_{ab} \\ V_{\bar{a}\bar{b}} & V_{\bar{a}b} \end{pmatrix}, \quad (2.4a)$$

and takes the form

$$V_{a\bar{b}} = e^{\mathcal{K}} \left\{ Z_a^{\bar{c}} \bar{Z}_{\bar{c}\bar{b}} - F_a \bar{F}_{\bar{b}} - R_{a\bar{b}c\bar{d}} \bar{F}^c F^{\bar{d}} + \mathcal{K}_{a\bar{b}} (F_c \bar{F}^c - 2|W|^2) \right\}, \quad (2.4b)$$

$$V_{ab} = e^{\mathcal{K}} \left\{ U_{abc} \bar{F}^c - Z_{ab} \bar{W} \right\}, \quad (2.4c)$$

in which

$$Z_{ab} = \mathcal{D}_a F_b, \quad U_{abc} = \mathcal{D}_a \mathcal{D}_b F_c, \quad (2.5)$$

where  $\mathcal{D}_a$  is the Kähler-covariant and geometrically-covariant derivative. Since the field space is Kähler, the Riemann tensor can be expressed in terms of ordinary derivatives of the Kähler potential as

$$R_{a\bar{b}c\bar{d}} = \mathcal{K}_{a\bar{b}c\bar{d}} - \mathcal{K}_{ac}^e \mathcal{K}_{\bar{b}\bar{d}e}. \quad (2.6)$$

## 2.2 Random supergravities

Creating a globally well-defined potential energy function depending on  $N$  fields is exponentially expensive at large  $N$ . However, to understand the behavior at a collection of critical points, including the particularly interesting case of metastable minima, only certain local data about the potential are necessary: it suffices to specify the first four derivatives of the Kähler potential  $\mathcal{K}$ , and the first three derivatives of the superpotential  $W$ , at each point of interest. By performing Taylor expansions of the  $\mathcal{N} = 1$  data at a set of well-separated points, one can construct an ensemble of Hessian matrices, and characterize the probability of metastability (or of any other outcome of interest) in this ensemble. In this approach, *no information* about correlations from point to point is retained. Understanding correlations in field space is left as a problem for future work.<sup>5</sup>

The essential assumption made in random supergravity approaches to the Hessian (2.4) is that the Kähler potential and the superpotential are real and holomorphic i.i.d. functions, respectively, on the moduli space [7, 16]. That is, expressing the Kähler potential via a Taylor series around a fixed origin,

$$\mathcal{K} = \mathcal{K}_0 + \mathcal{K}_a \phi^a + \mathcal{K}_{\bar{a}} \bar{\phi}^{\bar{a}} + \mathcal{K}_{a\bar{b}} \phi^a \bar{\phi}^{\bar{b}} + \dots, \quad (2.7)$$

the elements of each tensor  $\mathcal{K}_{ab\dots\bar{c}\bar{d}\dots}$  are taken to be independent and identically distributed variables: each element is drawn from some statistical distribution  $\Omega$ , and although the same distribution is used for every element, each element is drawn independently from the others (up to the symmetries of the tensor). We use the notation  $x \in \Omega(\mu, \sigma)$  to denote that the real number  $x$  is drawn from a distribution with mean  $\mu$  and standard deviation  $\sigma$ . When  $z$  is complex,  $z \in \Omega(\mu, \sigma)$  means that  $z = x e^{i\theta}$ , where  $x$  is a real number drawn from  $\Omega$  and the phase  $\theta$  is drawn from a uniform distribution. We will often work with normal distributions, though universality in random matrix theory ensures that most results will be independent of the details of the distribution  $\Omega$ , for sufficiently large  $N$ .

At a particular critical point of the potential, we can perform a Kähler transformation and coordinate redefinition to set

$$\mathcal{K} = 0, \quad \mathcal{K}_{a\bar{b}} = \delta_{a\bar{b}}, \quad F_a = \delta_a^1 F e^{i\vartheta_F}, \quad (2.8)$$

in which  $F$  is positive and  $\vartheta_F$  is an unimportant phase. The random supergravity approach is then to model the higher derivatives as i.i.d. variables,

$$\mathcal{K}_{a\bar{b}c} \in \Omega(0, \sigma), \quad \mathcal{K}_{a\bar{b}c\bar{d}} \in \Omega(0, \sigma), \quad \sigma = N^{-1/2}. \quad (2.9)$$

The choice  $\sigma = N^{-1/2}$  is purely for later convenience.

The covariant derivatives of the superpotential are likewise taken to be i.i.d. variables<sup>6</sup> with

$$Z_{ab} \in m_{\text{susy}} \Omega(0, \sigma), \quad U_{abc} \in m_{\text{susy}} \Omega(0, \sigma). \quad (2.10)$$

<sup>5</sup>See [17] for recent progress on incorporating global constraints.

<sup>6</sup>The requirement of being at a critical point necessarily spoils the i.i.d. assumption, as the potential is subject to the  $2N$  conditions  $\partial_a V = 0$  at that point. However, since these are  $\mathcal{O}(N)$  conditions on a matrix with  $\mathcal{O}(N^2)$  entries, at large  $N$  imposing the critical point equation does not significantly affect positivity properties [16].

**Figure 1.** Eigenvalue distributions for two classical matrix ensembles. The data displayed result from collections of 1000 matrices with  $200 \times 200$  i.i.d. entries with  $\sigma = 1/\sqrt{200}$ .

in which  $m_{\text{susy}}$  is a characteristic scale for supersymmetric mass terms. At generic critical points, we expect that  $m_{\text{susy}} \sim F$  (in Planck units).

Two classical ensembles of matrices are particularly relevant for our analysis and for the models of [7, 16]. The first is the complex Wigner ensemble [23–26], which consists of  $n \times n$  Hermitian matrices of the form

$$M = A + A^\dagger, \quad (2.11)$$

in which each element of  $A$  is an i.i.d. complex variable. The other relevant ensemble is the complex Wishart ensemble [27], consisting of  $n \times n$  Hermitian matrices of the form

$$M = AA^\dagger, \quad (2.12)$$

in which  $A$  is an  $n \times q$  matrix ( $q \geq n$ ) with i.i.d. complex entries. The eigenvalue spectra for these ensembles take on the characteristic shapes shown in figure 1.

The structure of the Hessian (2.4) and the special structure of the Riemann tensor (2.6) suggest that, under the i.i.d. assumptions (2.9) and (2.10), the various contributions to the Hessian can be approximated by these classical distributions and a constant shift matrix [16]

$$\begin{aligned}
 \mathcal{H} = & \underbrace{\begin{pmatrix} 0 & U_{ab1}\bar{F}^1 - Z_{ab}\bar{W} \\ \bar{U}_{\bar{a}\bar{b}1}F^{\bar{1}} - \bar{Z}_{\bar{a}\bar{b}}\bar{W} & 0 \end{pmatrix}}_{\approx \text{Wigner}} + F^2 \begin{pmatrix} -\mathcal{K}_{ab1\bar{1}} & 0 \\ 0 & \mathcal{K}_{\bar{a}\bar{b}1\bar{1}} \end{pmatrix} \\
 & + \underbrace{\begin{pmatrix} Z_a^{\bar{c}}\bar{Z}_{\bar{b}\bar{c}} & 0 \\ 0 & \bar{Z}_{\bar{a}}^c Z_{bc} \end{pmatrix}}_{\approx \text{Wishart}} + F^2 \underbrace{\begin{pmatrix} \mathcal{K}_{a1}^e \mathcal{K}_{\bar{b}1\bar{e}} & 0 \\ 0 & \mathcal{K}_{\bar{a}1}^{\bar{e}} \mathcal{K}_{b1\bar{e}} \end{pmatrix}}_{\approx \text{Wishart}} \\
 & + \underbrace{(F^2 - 2|W|^2)\mathbb{1} - F^2\delta_a^1\delta_{\bar{b}}^{\bar{1}} - F^2\delta_{\bar{a}}^{\bar{1}}\delta_b^1}_{\approx \text{shift}},
 \end{aligned} \quad (2.13)$$

where we are locally working in a basis such that (2.8) holds at the critical point under consideration. In [16], it was established that the typical spectrum of eigenvalues of an

**Figure 2.** Eigenvalue distributions for random matrix models of the i.i.d. Hessian  $\mathcal{H}^{\text{i.i.d.}} \approx \mathcal{H}^{\text{WWW}}$  (2.13) (taken with  $3|W|^2/F^2 = .01$ ) and of the Riemann contribution  $\mathcal{H}_R^{\text{i.i.d.}} \approx \mathcal{H}_R^{\text{WW}}$  (1.3). In both cases, the spectra are in units of  $|F|^2$ . Figure 2a is adapted from figure 3 of [16].

ensemble of i.i.d. supergravity Hessians is well-modeled by the sum

$$\mathcal{H}^{\text{i.i.d.}} \approx \mathcal{H}^{\text{WWW}} = \text{Wigner} + \text{Wishart} + \text{Wishart}. \quad (2.14)$$

The spectrum of the ensemble  $\mathcal{H}^{\text{WWW}}$  is shown in figure 2a. In [16], it was found that the probability for a generic critical point to be metastable scales as  $e^{-cN^p}$ , where  $p \approx 1.5$  for  $\mathcal{H}^{\text{i.i.d.}}$  and  $p \approx 1.9$  for  $\mathcal{H}^{\text{WWW}}$ .

This random supergravity approach must be modified when one or more of the i.i.d. assumptions (2.9) and (2.10) is invalid. Some form of modification is clearly necessary to give a detailed model of string compactifications, as the resulting supergravity data are expected to exhibit significant correlations. Although a complete incorporation of all such correlations is impossible given current knowledge, we can make considerable progress by incorporating information about the classical Kähler potential.

In the following sections, we revisit the supergravity Hessian (2.4) using ensembles of Kähler potentials for the classical metrics on Kähler moduli space in explicit Calabi-Yau compactifications. Since our focus is on how correlations in the Kähler geometry impact the Hessian, we retain an i.i.d. approach to the F-terms and focus on the Riemann contribution to the Hessian,  $\mathcal{H}_R$ , which can be analyzed without further modeling of the superpotential and its higher derivatives  $Z_{ab}$  and  $U_{abc}$ .

### 3 The Kähler moduli space of O3/O7 orientifolds

In this section, we review the Kähler moduli space of compactifications of type IIB string theory on O3/O7 orientifolds of Calabi-Yau manifolds. These compactifications are well-explored, and allow for a separation of scales between the masses of the stabilized complex structure moduli and Kähler moduli as in [20, 28]. We will assume that such a separation has been achieved and so limit our treatment to the Kähler moduli sector. In the following sections, we will make use of the corresponding classical Kähler potential to improve upon the i.i.d. treatments discussed in section 2.

After reviewing some of the basic properties of the moduli space, we provide expressions for the metric and Riemann curvature that will be useful for our scan of moduli spaces, and then prove a simple but important negativity property of the curvature contribution to the Hessian (2.4).

### 3.1 The Kähler cone

A compactification of type IIB string theory on a Calabi-Yau threefold yields an  $\mathcal{N} = 2$  theory in four dimensions.<sup>7</sup> The deformations of the Kähler structure, together with scalars provided by the  $p$ -form potentials  $C_4$ ,  $C_2$ , and  $B_2$ , form a quaternionic Kähler moduli space of real dimension  $4h^{1,1}$ , where  $h^{p,q}$  are the Hodge numbers of the Calabi-Yau. Reduction to an  $\mathcal{N} = 1$  theory is accomplished by the introduction of orientifold planes, and the structure of the resulting supergravity theory depends on which orientifold projection is used. We will assume an O3/O7 orientifold action, and moreover will take all of the divisors  $D^a$  of the Calabi-Yau to be even under the geometric involution (i.e.  $h_-^{1,1} = 0$ ), so that all Kähler deformations of the Calabi-Yau are projected in by the orientifold action.<sup>8</sup> In the resulting  $\mathcal{N} = 1$  theory, the 4-cycle volumes  $\tau^a$  are paired with R-R axions  $c^a = \int_{D^a} C_4$  to form the complex scalar components  $\rho^a = \tau^a + i c^a$  of  $h^{1,1}$  chiral superfields. The classical Kähler potential for the Kähler moduli space metric, at leading order in  $\alpha'$ , is given in terms of the volume  $\mathcal{V}$  of the Calabi-Yau by

$$\mathcal{K} = -2 \log \mathcal{V}. \quad (3.1)$$

If  $\{D^a\}$  is a basis of divisors of the Calabi-Yau, then the Kähler form of the Calabi-Yau can be expanded in terms of the Poincaré duals  $[D^a]$  of these divisors,

$$J = t_a [D^a]. \quad (3.2)$$

The volume of the Calabi-Yau is

$$\mathcal{V} = \frac{1}{3!} \int J^3 = \frac{1}{3!} \kappa^{abc} t_a t_b t_c, \quad (3.3)$$

in which  $\kappa^{abc} = D^a \cdot D^b \cdot D^c$  are the triple intersection numbers of the divisors. The volume of the divisor  $D^a$  is then

$$\tau^a = \frac{\partial \mathcal{V}}{\partial t_a} = \frac{1}{2} \kappa^{abc} t_b t_c. \quad (3.4)$$

The Calabi-Yau volume  $\mathcal{V}$  and the Kähler potential on moduli space are easily expressed in terms of the variables  $t_a$ , which parameterize the volumes of 2-cycles. However, the 2-cycle volumes do not provide good Kähler coordinates in O3/O7 projections, in that we cannot write the metric as  $\partial_{w^a} \bar{\partial}_{\bar{w}^b} \mathcal{K}$  where  $w^a$  is a complexification of  $t_a$ . Because the  $\tau^a$ , rather than the  $t_a$ , provide good coordinates on moduli space, we find it convenient to use lowered indices for 2-cycle volumes, even though this goes against convention.

<sup>7</sup>See, for example, [29–31] for reviews of the effective field theories arising in these constructions and in their orientifolds.

<sup>8</sup>For recent work in classifying consistent orientifold involutions for Calabi-Yau hypersurfaces in toric varieties, see [32].

**Figure 3.** A non-simplicial cone in three dimensions. The cone is generated by the five rays originating from the apex.

The Kähler moduli space is specified by the requirement that the volumes of all holomorphic curves and divisors, and of the Calabi-Yau itself, are positive. Since the volumes of such objects are of the form  $\int J^k$ , where  $J$  is the Kähler form (3.2), the moduli space is a cone: if  $\vec{t} = (t_1, \dots, t_{h^{1,1}})$  is a point in the moduli space, then so is  $\lambda \vec{t}$  for  $\lambda > 0$ .

The space of curves also forms a cone, called the Mori cone, that is generated by a finite set of curves  $C_i$ . The condition that all curves have positive volume is equivalent to the condition

$$\int_{C_i} J > 0, \quad \forall C_i. \quad (3.5)$$

The condition (3.5) suffices to ensure positivity of the volumes of all divisors and of the Calabi-Yau, and so the Kähler cone is the set of  $t_a$  that satisfy (3.5). Writing the intersections of the divisors with the curves  $C_i$  as

$$Q_i^a = D^a \cdot C_i, \quad (3.6)$$

a sufficient condition to be in the interior of the Kähler cone is

$$Q_i^a t_a > 0, \quad \forall i. \quad (3.7)$$

In general, there are more than  $h^{1,1}$  generators of the Mori cone, and so  $Q$  is not a square matrix (though see the discussion in appendix A). In this case the Kähler cone is said to be *non-simplicial*, meaning that the number of generators of the cone is larger than the dimension of the cone (see figure 3). When  $Q$  is square, the Kähler cone is simplicial.

### 3.2 The metric and curvature on moduli space

The metric and curvature on moduli space follow from taking derivatives of the Kähler potential with respect to the Kähler coordinates  $\rho^a = \tau^a + i c^a$ . However, since the classical Kähler potential is independent of the axions  $c^a$ , we can make the replacement

$$\frac{\partial}{\partial \rho^a} \rightarrow \frac{1}{2} \frac{\partial}{\partial \tau^a}. \quad (3.8)$$

Expressed as (3.3), the volume of the Calabi-Yau, and hence the Kähler potential, is only an implicit function of the coordinates  $\tau^a$ . We therefore make extensive use of the chain rule

$$\frac{\partial}{\partial \tau^a} = A_{ba} \frac{\partial}{\partial t_b}, \quad A_{ba} := \frac{\partial t_a}{\partial \tau^b}. \quad (3.9)$$

One can show that  $A$  has mostly negative eigenvalues, with signature  $(1, h^{1,1} - 1)$ . The inverse of  $A$  takes the simple form<sup>9</sup>

$$(A^{-1})^{ab} = \frac{\partial \tau^a}{\partial t_b} = \frac{\partial^2 \mathcal{V}}{\partial t_a \partial t_b} = \kappa^{abc} t_c. \quad (3.10)$$

Note that due to the symmetry properties of  $\kappa^{abc}$ ,  $A^{-1}$  and  $A$  are symmetric matrices.

Since the coordinates  $\tau^a$  are defined via (3.4),  $A_{ab}$  is difficult to calculate directly from its definition (3.9), but can be calculated by inverting (3.10). In what follows, we will perform the inversion numerically, as the analytic computation is expensive when  $h^{1,1}$  is large. Higher derivatives of the Kähler potential will involve differentiating  $A_{ab}$ , and numerical differentiation can be avoided by using (3.10):

$$\frac{\partial A_{bc}}{\partial t_a} = -A_{bd} \frac{\partial (A^{-1})^{de}}{\partial t_a} A_{ec} = -A_{bd} \kappa^{ade} A_{ec}. \quad (3.11)$$

Using the identities  $A_{ab} \tau^b = \frac{1}{2} t_a$  and  $t_a \tau^a = 3\mathcal{V}$ , the relevant derivatives of the Kähler potential take the form

$$\mathcal{K}_{a\bar{b}} = \frac{t_a t_b}{8\mathcal{V}^2} - \frac{A_{ab}}{4\mathcal{V}}, \quad (3.12a)$$

$$\mathcal{K}^{a\bar{b}} = 4\tau^a \tau^b - 4\mathcal{V} (A^{-1})^{ab}, \quad (3.12b)$$

$$\begin{aligned} \mathcal{K}_{ac}{}^e \mathcal{K}_{\bar{b}\bar{d}\bar{e}} &= \frac{1}{32\mathcal{V}^4} t_a t_c t_b t_d - \frac{1}{64\mathcal{V}^3} [6A_{(ac} t_b t_d) + A_{ac} t_b t_d + A_{bd} t_a t_c] \\ &\quad + \frac{3}{32\mathcal{V}^2} A_{ac} A_{bd} - \frac{1}{8\mathcal{V}^2} t_{(a} S_{bcd)} - \frac{1}{16\mathcal{V}} S_{ace} S_{bdf} (A^{-1})^{ef}, \end{aligned} \quad (3.12c)$$

$$\begin{aligned} \mathcal{K}_{a\bar{b}\bar{c}\bar{d}} &= \frac{3}{64\mathcal{V}^4} t_a t_b t_c t_d - \frac{3}{16\mathcal{V}^3} A_{(ab} t_c t_d) + \frac{3}{32\mathcal{V}^2} A_{(ab} A_{cd)} \\ &\quad - \frac{1}{8\mathcal{V}^2} t_{(a} S_{bcd)} - \frac{3}{16\mathcal{V}} S_{e(ab} S_{cd)f} (A^{-1})^{ef}, \end{aligned} \quad (3.12d)$$

in which we have defined the totally symmetric tensor

$$S_{abc} = \kappa^{def} A_{ad} A_{be} A_{cf}, \quad (3.13)$$

and  $M_{(a_1 \dots a_n)}$  denotes symmetrization of  $M$ . Combining (3.12d) and (3.12c) gives the full Riemann tensor (2.6)

$$\begin{aligned} R_{a\bar{b}\bar{c}\bar{d}} &= \frac{1}{64\mathcal{V}^4} t_a t_b t_c t_d - \frac{1}{64\mathcal{V}^3} [6A_{(ac} t_b t_d) - A_{ac} t_b t_d - A_{bd} t_a t_c] \\ &\quad + \frac{3}{32\mathcal{V}^2} [A_{(ab} A_{cd)} - A_{ac} A_{bd}] - \frac{1}{8\mathcal{V}} S_{ea(b} S_{d)c f} (A^{-1})^{ef}. \end{aligned} \quad (3.14)$$

<sup>9</sup>Our notation differs from that appearing elsewhere in the literature, where  $A$  and its inverse are interchanged.

### 3.3 The Riemann contribution to the Hessian

The Hessian (2.4) receives a contribution from the Riemann tensor on moduli space contracted with F-terms (2.4b),

$$(\mathcal{H}_R)_{a\bar{b}} := -e^{\mathcal{K}} R_{a\bar{b}c\bar{d}} \bar{F}^c F^{\bar{d}}, \quad (3.15)$$

This contribution in turn breaks into two pieces involving the third and fourth derivatives of the Kähler metric (2.6),

$$\mathcal{H}_R = \mathcal{H}_{\mathcal{K}^{(3)}} + \mathcal{H}_{\mathcal{K}^{(4)}} \quad (3.16)$$

where

$$(\mathcal{H}_{\mathcal{K}^{(4)}})_{a\bar{b}} := -e^{\mathcal{K}} \mathcal{K}_{a\bar{b}c\bar{d}} \bar{F}^c F^{\bar{d}}, \quad (\mathcal{H}_{\mathcal{K}^{(3)}})_{a\bar{b}} := e^{\mathcal{K}} \mathcal{K}_{ac}{}^e \mathcal{K}_{\bar{b}\bar{d}e} \bar{F}^c F^{\bar{d}}. \quad (3.17)$$

Although the presentation (3.12c) does not make the positivity of  $\mathcal{H}_{\mathcal{K}^{(3)}}$  manifest, it does demonstrate that  $\mathcal{H}_{\mathcal{K}^{(3)}}$  and  $\mathcal{H}_{\mathcal{K}^{(4)}}$  have very similar structures. This similarity is a manifestation of the fact that the higher derivatives of the Kähler potential cannot be taken to be entirely independent, a fact which will have important implications for the spectrum of the Hessian. Indeed, both  $\mathcal{H}_{\mathcal{K}^{(4)}}$  and  $\mathcal{H}_{\mathcal{K}^{(3)}}$  will be seen to exhibit dramatic tails in their eigenvalue distributions that are cancelled to some degree in the full curvature contribution to the Hessian,  $\mathcal{H}_R = \mathcal{H}_{\mathcal{K}^{(3)}} + \mathcal{H}_{\mathcal{K}^{(4)}}$ . Even so, the residual tails in  $\mathcal{H}_R$  are substantial.

Despite the relative complexity of (3.14), the resulting contribution to the Hessian,  $\mathcal{H}_R$ , exhibits a striking property: when  $F \neq 0$ ,  $\mathcal{H}_R$  always has at least one strictly negative eigenvalue. The proof of this is quite simple, and relies on the fact that the Kähler metric is a homogeneous function of the Kähler coordinates. Indeed, under  $\rho^a \rightarrow \lambda \rho^a$  we have

$$\mathcal{K}_{a\bar{b}} \rightarrow \lambda^{-2} \mathcal{K}_{a\bar{b}}. \quad (3.18)$$

In order to show that  $\mathcal{H}_R$  has a negative eigenvalue, it suffices to show that  $(\mathcal{H}_R)_{a\bar{b}} \xi^a \bar{\xi}^b < 0$  for some  $\xi^a$ . Taking  $\xi^a = \tau^a$ , we have

$$\tau^a \tau^{\bar{b}} (\mathcal{H}_R)_{a\bar{b}} = \frac{1}{4} e^{\mathcal{K}} \tau^a \tau^{\bar{b}} \left\{ \frac{\partial \mathcal{K}_{c\bar{f}}}{\partial \tau^a} \frac{\partial \mathcal{K}_{\bar{d}e}}{\partial \tau^{\bar{b}}} \mathcal{K}^{e\bar{f}} - \frac{\partial}{\partial \tau^a} \frac{\partial}{\partial \tau^{\bar{b}}} \mathcal{K}_{c\bar{d}} \right\} \bar{F}^c F^{\bar{d}}. \quad (3.19)$$

If  $f(x^1, \dots, x^n)$  is a homogeneous function of degree  $n$ , then it satisfies the well known relation

$$x^i \frac{\partial f}{\partial x^i} = n f. \quad (3.20)$$

Because  $\mathcal{K}_{a\bar{b}}$  is a homogeneous function of degree  $-2$ , we have

$$\tau^a \frac{\partial \mathcal{K}_{c\bar{f}}}{\partial \tau^a} = -2 \mathcal{K}_{c\bar{f}}. \quad (3.21)$$

On the other hand,  $\partial \mathcal{K}_{c\bar{d}} / \partial \tau^b$  is a homogeneous function of degree  $-3$ , so

$$\tau^a \frac{\partial}{\partial \tau^a} \left[ \frac{\partial \mathcal{K}_{c\bar{d}}}{\partial \tau^b} \right] = -3 \frac{\partial \mathcal{K}_{c\bar{d}}}{\partial \tau^b}. \quad (3.22)$$

Together,

$$\tau^a \tau^{\bar{b}} (\mathcal{H}_R)_{a\bar{b}} = \frac{1}{4} e^{\mathcal{K}} \left\{ 4 \mathcal{K}_{c\bar{f}} \mathcal{K}_{\bar{d}e} \mathcal{K}^{e\bar{f}} - 6 \mathcal{K}_{c\bar{d}} \right\} \bar{F}^c F^{\bar{d}} = -\frac{1}{2} e^{\mathcal{K}} |F|^2. \quad (3.23)$$

This is non-positive, and so the smallest eigenvalue  $\lambda_{\min}(\mathcal{H}_R)$  obeys

$$\lambda_{\min}(\mathcal{H}_R) \leq 0, \quad (3.24)$$

with equality only when  $F = 0$ , in which case  $\mathcal{H}_R$  is identically zero. It is easy to show that this generalizes: if the metric is a homogeneous function of negative degree, then  $\mathcal{H}_R$  will always have at least one negative eigenvalue. Moreover, this result holds for Kähler moduli spaces in other string theories. However, quantum corrections to the Kähler potential will necessarily spoil the homogeneity of the metric (indeed, the homogeneity of the Kähler metric is closely related to no-scale structure) and so (3.24) is guaranteed to hold only at weak coupling and large volume.

The negativity result (3.24) is quite different from the expectation of the random supergravity approach discussed in section 2.2. In particular, the i.i.d. model for the curvature contribution to the Hessian is well-modeled by the sum of a Wishart matrix and a Wigner matrix, as in (1.3) [16]. The resulting distribution of eigenvalues is shown in figure 2b. Although the vast majority of the members of an ensemble of such matrices will have at least one negative eigenvalue, there is a small probability  $P \sim e^{-cN^p}$  that a randomly chosen matrix will be positive-definite.

We now turn to constructing an ensemble of Kähler metrics on Calabi-Yau hypersurfaces, where we will find even more dramatic deviations from the model (1.3).

## 4 Method

Although the classical metric on the Kähler moduli space of a Calabi-Yau compactification is given explicitly in terms of 2-cycle volumes and triple intersection numbers by (3.12a), for  $h_{1,1} \gtrsim 5$  it is difficult to extract meaningful characteristics of the metric analytically. Moreover, for the reasons explained in section 1, it is most useful to determine general statistical properties that hold for most or all members of an ensemble of Calabi-Yau manifolds.

Our approach is to construct an ensemble of classical Kähler metrics  $\mathcal{K}_{a\bar{b}}$  that describe the Kähler moduli spaces of Calabi-Yau hypersurfaces in toric varieties. Moreover, by combining this explicit metric data with i.i.d. F-terms, we construct an ensemble of curvature contributions  $\mathcal{H}_R$  to the supergravity Hessian matrix. In this section, we provide a detailed prescription for generating these ensembles. In short, we triangulate a number of reflexive polytopes to obtain the topological data of desingularized Calabi-Yau hypersurfaces in toric varieties, making use of the Kreuzer-Skarke database [18] generated by PALP [33, 34], and then sample the associated Kähler cones.

### 4.1 Generating metrics

The functional form of the classical Kähler potential  $\mathcal{K}$  is fully specified by the intersection numbers, which in the case of a Calabi-Yau hypersurface in a toric variety are determined by a triangulation of the associated polytope (see appendix A for a brief review of toric geometry). The computational cost of the triangulation process grows very quickly with the number of Kähler moduli. In appendix B, we present an efficient triangulation algorithm that allows us to study hypersurfaces with  $h^{1,1} \lesssim 25$  using modest computational resources.

The relevant outputs of the triangulation algorithm, for a given Calabi-Yau, are the intersection numbers among divisors,  $\kappa^{abc}$ , and between the divisors and generators of the Mori cone,  $Q_i^a$ . The Kähler cone is generated by a finite number  $\nu$  of  $h^{1,1}$ -dimensional vectors  $\vec{n}_\alpha$ , with  $\alpha = 1, \dots, \nu$ . That is, every point in the interior of the cone can be written in the form

$$\vec{t} = s_\alpha \vec{n}_\alpha \quad (4.1)$$

for positive  $s_\alpha$ . In general, there may be more than  $h^{1,1}$  generators  $\vec{n}_\alpha$  (i.e.,  $\nu > h^{1,1}$ ) in which case the cone is non-simplicial (see figure 3).

Given the intersection numbers  $\kappa^{abc}$ , the components of the Kähler metric, expressed in a fixed coordinate system, are determined by the 2-cycle volumes  $t_a$ , i.e. by the vacuum expectation values of the Kähler moduli. Thus, to build an ensemble of Kähler metrics arising at points in the moduli space of any one Calabi-Yau threefold, we must specify a collection of points inside the Kähler cone. Next, to assemble the larger ensemble of metrics arising at points in the moduli spaces of a collection of distinct threefolds, we must specify how we choose a set of polytopes, a set of associated triangulations, and a collection of points in the Kähler cone determined by each triangulation.

Schematically, the probability of some measurable outcome  $\mathcal{O}$  (e.g., a given hierarchy in the eigenvalues of the metric) may be written in the form

$$P(\mathcal{O}) = P(\text{polytope}) \times P(\text{triangulation}) \times P(t_i) \quad (4.2)$$

where  $P(t_i)$  denotes the measure chosen for sampling the Kähler cone. The first two factors in (4.3) encode the relative weighting given to distinct choices of topological data. Lacking any principle to determine this measure, we give equal weight to each distinct set of intersection numbers obtained in our approach.

Next, one would aspire to choose a sampling measure  $P(t_i)$  that reflects broad characteristics of the actual distribution  $P_{\text{vacua}}(t_i)$  of string vacua inside the Kähler cone, which can be written on general grounds as

$$P_{\text{vacua}}(t_i) = P_{\text{geometric}}(t_i) \times P_{\text{selection}}(t_i), \quad (4.3)$$

where the first factor denotes the geometric measure induced on the Kähler cone by the Kähler metric on moduli space, and tends to be peaked near the boundaries of the cone.<sup>10</sup> The second factor encodes additional selection effects: for example, one might expect that string vacua are more common near the walls of the Kähler cone because the superpotential for the Kähler moduli is exponentially small when all volumes are large. (Here we have in mind the general lore that corrections are important where they are not computable [35].) Characterizing  $P_{\text{selection}}$  requires a complete understanding of dynamics, which is inaccessible at present. As a result, we must be agnostic about whether the sampling measure  $P(t_i)$  that we choose provides a reasonable approximation to  $P_{\text{vacua}}(t_i)$ .

The choice of  $P(t_i)$  can be encoded in the choice of coefficients  $s_\alpha$  appearing in (4.1). Because the Kähler cone has infinite volume, it is necessary to impose a long-distance cutoff

<sup>10</sup>The volume of moduli space as measured by the Kähler metric is divergent, even on a constant volume slice, due to divergences of the metric near the boundaries of the Kähler cone.

on the sampled region. Since the metric and its derivatives are homogeneous functions of the 2-cycle volumes, taking  $s_\alpha$  to be within a finite interval can provide a representative sampling of the cone. A natural choice is to draw  $s_\alpha$  from a uniform distribution, and this is the choice that we make for much of our analysis. However, with this prescription the ratios of 2-cycle volumes remain within a comparatively small range, and potentially interesting behavior near the walls of the Kähler cone, where the ratios of 2-cycle volumes are large, is not fully explored. To address this deficiency we draw the  $s_\alpha$  from a logarithmic distribution for a portion of our dataset.

## 4.2 Constructing curvature Hessians

The method presented in section 4.1 suffices to generate an ensemble of Kähler metrics, but in order to specify a scalar potential on field space we must also give a prescription for determining  $W$  and its derivatives. As discussed previously, we are assuming a hierarchical separation of scales between the Kähler moduli and other closed-string moduli, and therefore the effective number of chiral multiplets is  $N = h^{1,1}$ .

The curvature contribution  $\mathcal{H}_R$  to the Hessian, (3.15), depends on the superpotential only through the  $F^a$ , while the remainder of the Hessian receives contributions from  $\partial_a \partial_b W$  and  $\partial_a \partial_b \partial_c W$  as well. For this reason, we focus in this work on the properties of  $\mathcal{H}_R$ , which are more directly geometric, and less affected by our limited knowledge of the superpotential, than the properties of the full Hessian  $\mathcal{H}$ . Developing an accurate model of the superpotential and characterizing the resulting Hessian matrix, perhaps along the lines of [36], is an important problem for the future.

To construct  $\mathcal{H}_R$ , we take the F-terms  $F_a$  of the Kähler moduli  $\rho^a$ , expressed in the toric basis, to be i.i.d. variables (cf. (2.8)),

$$F_a \in F \Omega \left( 0, 1/\sqrt{h^{1,1}} \right). \quad (4.4)$$

The Kähler metric and Riemann tensor scale homogeneously with the volume, so that the Hessian for the canonically-normalized fields scales as

$$\mathcal{H}_R^c \sim \frac{F^2}{\mathcal{V}^{4/3}}. \quad (4.5)$$

We are interested in the shape of the spectrum of  $\mathcal{H}_R$ , rather than the overall scale, so throughout we report on the spectrum of the rescaled curvature Hessian for the canonically-normalized fields,

$$\mathcal{H}_R^{\text{CY}} = \frac{\mathcal{V}^{4/3}}{F^2} \mathcal{H}_R^c. \quad (4.6)$$

## 5 Results

Following all of the steps laid out in the previous sections, we can now present the eigenvalue spectra of the Kähler metrics  $\mathcal{K}_{a\bar{b}}$  and the curvature Hessians  $\mathcal{H}_R^{\text{CY}}$  for a collection of 120 Calabi-Yau hypersurfaces in toric varieties. Although most of this section pertains to O3/O7 projections of type IIB, section 5.6 contains a brief analysis of the curvature Hessians in other corners of the string landscape.

**Figure 4.** The nine smallest eigenvalues, coded by color, of each of  $10^5$  metrics on the Kähler moduli space of a threefold with  $h^{1,1} = 15$ .

### 5.1 Metric eigenvalue spectra

To study the spectrum of metric eigenvalues we fix the basis of Kähler moduli to a basis of independent toric divisors, as discussed in appendix A. We then compute the eigenvalues of the moduli space metric in this basis, projected to the  $\mathcal{V} = 1$  hypersurface of the Kähler cone. The metric scales homogeneously with the volume, so restricting to any other fixed value of the volume will only change the overall scale of the metric eigenvalues. In figures 4 and 5, we present the eigenvalue spectra for an ensemble of moduli space metrics for a Calabi-Yau threefold with  $h^{1,1} = 15$ . There are two notable features that appear in all of the examples we examined: the spectra manifest large hierarchies, with the largest and smallest eigenvalues being very different from the median, and the distributions of the smallest few eigenvalues are highly peaked.

The sharply-localized distributions of the smallest few eigenvalues can be attributed to the particular dependence of  $\mathcal{V}$  on the 4-cycle volumes. It is convenient to work in a basis that diagonalizes the matrix  $A_{ab} = -\partial^2 \mathcal{V} / \partial \tau^a \partial \tau^b$ . We refer to the diagonalized A-matrix as  $\hat{A}$ . In figure 6a we show the relationship between the largest 4-cycle volume  $\tau_L$  and the compactification volume  $\mathcal{V}$ , where  $\tau_L$  is measured in a basis where  $A_{ab} = \hat{A}_{ab}$ . Because  $\mathcal{V}$  is approximately linear in  $\tau_L^{3/2}$ , it appears that the single parameter  $\tau_L$  controls the overall volume of the Calabi-Yau in this region of moduli space. The smallest eigenvalue of the metric,  $\lambda^g$ , is strongly correlated with  $\mathcal{V}$  — see figure 6b — and so the rescaling to  $\mathcal{V} = 1$  makes the distribution of  $\lambda^g$  highly localized. The smaller 4-cycles, on the other hand, do not change the volume very much, and the corresponding metric eigenvalues have a larger spread. As  $\tau_L$  increases, changes to the other 4-cycle volumes result in a smaller relative change to the overall volume, and so these tendencies become more pronounced.

The hierarchies in the metric eigenvalues are an intriguing and important feature that we will discuss further in the following sections.

**Figure 5.** The largest eigenvalues and the entire spectrum of the metric on the Kähler moduli space of a threefold with  $h^{1,1} = 15$ . In (a), the tail of the distribution was truncated to demonstrate the bulk of the distribution. The entire spectrum has support from  $2.6 \times 10^{-5}$  to  $1.2 \times 10^9$ .

**Figure 6.** Scalings of the volume and of the smallest metric eigenvalue with the largest 4-cycle volume,  $\tau_L$ . Both relations are approximately linear in this regime.

## 5.2 The curvature Hessian in an example

We next turn to examining the curvature contribution  $\mathcal{H}_R^{\text{CY}}$  (3.17) to the Hessian matrices in our ensemble. We will begin with the example of a particular Calabi-Yau hypersurface with  $h^{1,1} = 25$ , which we call  $\mathcal{Y}_{25}$ .

The eigenvalue spectrum of  $\mathcal{H}_R^{\text{CY}}$ , which we denote by  $\rho_R$  for brevity, is shown for the example of  $\mathcal{Y}_{25}$  in figures 7, 8, and figure 9. The spectrum exhibits dramatic tails, as illustrated in figure 8. The bulk of the eigenvalue spectrum, with the tails removed to emphasize the shape near the peak of the spectrum, appears in figure 7, while a logarithmic plot of the entire spectrum is shown in figure 9.

Although  $\rho_R$  displays significant tails in both directions, the tail towards negativity is substantially longer than the tail towards positivity. This may come as a surprise, given the positive-semidefinite contribution to  $\mathcal{H}_R^{\text{CY}}$  coming from  $\mathcal{H}_{\mathcal{K}^{(3)}}^{\text{CY}}$  (3.17). Indeed, the eigenvalue distribution for  $\mathcal{H}_{\mathcal{K}^{(3)}}^{\text{CY}}$  for  $\mathcal{Y}_{25}$  is positive and exhibits large tails towards

**Figure 7.** Distribution of eigenvalues of the curvature contribution to the Hessian  $\mathcal{H}_R^{\text{CY}}$  in an ensemble of 5000 curvature Hessians derived from  $\mathcal{Y}_{25}$ , a Calabi-Yau with  $h^{1,1} = 25$ . The tails of the distribution extend for a few decades in either direction (see figure 8) and so have been truncated to make the bulk of the spectrum more visible. This distribution is to be contrasted with figure 2b, which is the distribution of eigenvalues for the Wigner+Wishart ensemble suggested by the null hypothesis.

positivity (see figure 10). However, because of the correlations between  $\mathcal{H}_{\mathcal{K}^{(3)}}^{\text{CY}}$  and  $\mathcal{H}_{\mathcal{K}^{(4)}}^{\text{CY}}$ , this positive tail is almost entirely removed in  $\mathcal{H}_R^{\text{CY}}$ , and the longest tail that remains is the tail towards negativity. These correlations can be seen explicitly in the similar structures in the derivatives of the Kähler potential (3.12c) and (3.12d). Indeed, the form of the combined Riemann tensor (3.14) demonstrates that significant cancellations have occurred.

Although we have focused on a particular example,  $\mathcal{Y}_{25}$ , the bulk of the spectra of  $\mathcal{H}_R^{\text{CY}}$  calculated on other Calabi-Yau manifolds are qualitatively very similar, especially for larger  $h^{1,1}$  (see figure 11). However, the tails of the distributions behave in quantitatively different ways: as we demonstrate in section 5.4, the greater the curvature of moduli space, the longer the corresponding tail of  $\mathcal{H}_R^{\text{CY}}$ .

### 5.3 Evidence for heavy-tailed spectra

The tails in  $\rho_R$  are clearly extensive — see figure 7. Indeed, the kurtosis of our sample of  $\mathcal{H}_R^{\text{CY}}$  on  $\mathcal{Y}_{25}$  is 230. In this section we quantify the extent of these tails in comparison to those in a number of reference distributions.

Comparison of the quantiles of the left tail of  $\rho_R$  to the quantiles of a half-normal distribution (figure 12) establishes that the tails of  $\rho_R$  contain more of the population than do the tails of a half-normal distribution. The kurtosis of the left tail ( $K \approx 149$ ) is much larger than that of a half-normal distribution ( $K \approx 3.87$ ), and the kurtosis of the right tail is also significant ( $K \approx 77.4$ ). In the remainder of this section we will focus on the tail towards negativity and so for graphical purposes, and only within this section, we

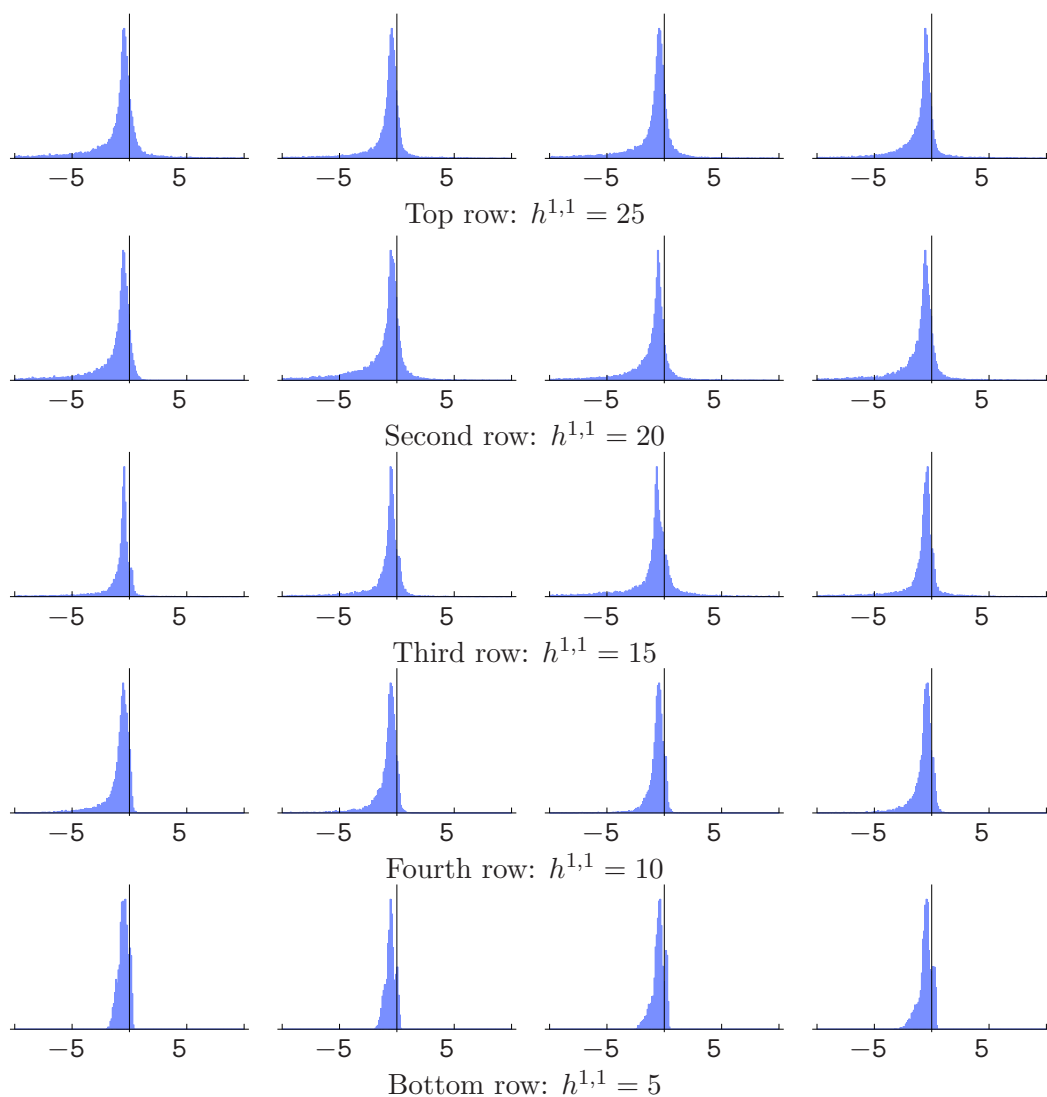

**Figure 8.** The spectra of minimum and maximum eigenvalues of  $\mathcal{H}_R^{\text{CY}}$  for  $\mathcal{Y}_{25}$ . For our sample, the minimum eigenvalues lie in the range  $[-2573, -3.2]$  and the maximum eigenvalues lie in the range  $[-.03, 167]$ .

**Figure 9.** Distribution of eigenvalues of the curvature contribution to the Hessian  $\mathcal{H}_R^{\text{CY}}$  and  $\mathcal{H}_R^{\text{WW}}$ , presented on a logarithmic scale. Note the lengthy tail toward negativity in the spectrum of  $\mathcal{H}_R^{\text{CY}}$ .

**Figure 10.** The spectra of the  $\mathcal{K}^{(3)}$  and  $\mathcal{K}^{(4)}$  contributions to  $\mathcal{H}_R^{\text{CY}}$  for  $\mathcal{Y}_{25}$ . The eigenvalues of  $\mathcal{H}_{\mathcal{K}^{(4)}}^{\text{CY}}$  can be of either sign, but only the negative eigenvalues have been plotted.  $\mathcal{H}_{\mathcal{K}^{(3)}}^{\text{CY}}$  is non-negative.

**Figure 11.** Distributions of eigenvalues  $\mathcal{H}_R^{\text{CY}}$  for a collection of Calabi-Yau manifolds. The tails of all of the distributions have been truncated to focus on the bulks of the distributions, which display common features consistent with universality.

will reverse the sign of  $\rho_R$  and shift the origin, so that the tail toward negativity in  $\rho_R$  is displayed extending to the right and peaking at zero.

By definition, a distribution is *heavy-tailed* when the tail is not exponentially bounded. Specifically, the survival (or tail) function of a distribution with probability distribution function (pdf)  $f$  is defined as

$$S(x) = \int_x^\infty dt f(t) . \quad (5.1)$$

The distribution is heavy-tailed if and only if for all  $\gamma > 0$ ,  $e^{\gamma x} S(x)$  diverges as  $x \rightarrow \infty$ . A canonical example of a heavy-tailed distribution is the Pareto distribution, for which the pdf  $f_{\beta;k}(x) = \beta k^\beta x^{-\beta-1}$  has support for  $x > k$ . For a normal distribution,  $e^{\gamma x} S(x) \rightarrow 0$  for any  $\gamma > 0$ , so the tails are not heavy. Exponential distributions  $f_\kappa = \kappa e^{-\kappa x}$  ( $\kappa > 0$ )

**Figure 12.** Quantiles of the left half of the spectrum  $\rho_R$  of eigenvalues of  $\mathcal{H}_R^{\text{CY}}$  computed in the example of  $\mathcal{Y}_{25}$ , against the same quantiles of a half-normal distribution  $\mathcal{N}_{\sigma}$ . The variance of  $H$  is chosen to give the best fit to the left tail of  $\rho_R$ . The dashed line is the curve that would result if  $\rho_R$  were half-normal.

**Figure 13.** (a): hazard functions for the last 10% of the distribution of  $\mathcal{H}_R^{\text{CY}}$  eigenvalues of  $\mathcal{Y}_{25}$  compared to best-fit half-normal, exponential, and power (Pareto) distributions. (b): goodness of fits ( $\chi^2$  per degree of freedom) of the hazard functions of  $\rho_R$  and of an exponential distribution to the form  $a + b x^{1+w}$ . Nonnegative concavity ( $w \geq 0$ ) in the case of  $\rho_R$  is rejected with overwhelming significance.

are a marginal case in which the limit vanishes, diverges, or converges to a finite value depending on whether  $\gamma$  is less than, greater than, or equal to  $\kappa$ .

A sufficient condition for a distribution to be heavy-tailed is that the hazard function  $h(x) := -\log S(x)$  is strictly concave downward. In figure 13a, we compare simulated hazard functions for the Pareto, half-normal, and exponential distributions to that of the last 10% of the left (negative) tail of the eigenvalue spectrum  $\rho_R$  of  $\mathcal{H}_R^{\text{CY}}$  computed for  $\mathcal{Y}_{25}$ . The hazard curves for the half-normal and power law distributions are strictly concave up and down, indicating light and heavy tails, respectively. The simulation of the hazard function for the exponential distribution does not clearly possess either concavity, and indeed the analytic result is  $h(x) = \kappa x$ .

The hazard function for  $\rho_R$  in figure 13 appears to be very slightly concave downward. A straightforward way to determine the concavity is to fit the hazard function to the form  $\hat{h} = a + bx^{1+w}$ . When  $w > 0$ , the model curve is concave upward, while when  $w < 0$ , the model curve is concave downward. In figure 13b, we show the  $\chi^2$  calculated from the best fit for a variety of values of  $w$ , indicating that the data are well-fitted by a curve that is concave down: by this measure,  $w \geq 0$  is excluded with extremely high confidence. A rough estimate of errors was obtained by subdividing the populations into five equal groups and combining the resulting hazard functions using the standard error.

However, using a parametric test for concavity is potentially problematic, as a concave-upward curve may in principle give a better fit to the data. A non-parametric test for concavity was described in [37]. Given a function  $y = f(x)$  and three points  $\{x_1, x_2, x_3\}$ , the concavity  $\mathcal{C}(x_1, x_2, x_3)$  is equal to +1 (−1) if the quadratic interpolation between the three points  $(x_1, y_1)$ ,  $(x_2, y_2)$ , and  $(x_3, y_3)$  is concave up (down), and equals 0 if the points are collinear. The method described in [37] yields an approximation to the expectation value of the concavity of a function. For the hazard function of  $\rho_R$ , sampled with 100 points, we find  $\langle \mathcal{C} \rangle = -0.62 \pm .06$ , giving strong evidence for downward concavity. Removing the points in the beginning of the distribution (which constitute the bulk of the distribution rather than the tail) or the end (which are statistically limited) tends to increase the significance of concavity. For comparison, an analysis for the hazard function of a corresponding amount of simulated data from an exponential distribution gives  $\langle \mathcal{C} \rangle = 0.02 \pm 0.06$ , and so an absence of curvature cannot be statistically rejected.

In summary, the eigenvalue spectrum  $\rho_R$  of  $\mathcal{H}_R^{\text{CY}}$  in the example of  $\mathcal{Y}_{25}$  has large positive excess kurtosis (i.e., is leptokurtic), with much longer tails than those of a normal distribution. Moreover, from the negative concavity of the hazard function we conclude that  $\rho_R$  is in fact a heavy-tailed distribution, with a survival function that falls off more slowly than any exponential.

While we will not present here the corresponding analyses for other examples of Calabi-Yau threefolds, we find similarly pronounced tails in the eigenvalue spectra  $\rho_R$  of  $\mathcal{H}_R^{\text{CY}}$  in all of the threefolds. Indeed, in an ensemble of threefolds with  $h^{1,1} = 10, \dots, 25$  and five threefolds at each  $h^{1,1}$ , we find that the average best fit value to  $\hat{h} = a + bx^{1+w}$  is  $w = -0.52 \pm 0.15$ .

We find comparable results for the metric eigenvalue spectrum as well: not only are the tails of the metric distributions quite extensive (see figure 5b), they are formally heavy.

## 5.4 Explaining the tails in the spectra

Having established the existence of heavy tails in the spectra  $\rho_R$  of  $\mathcal{H}_R^{\text{CY}}$  in Calabi-Yau hypersurface examples, we turn to explaining the causes of these tails. From the form  $(\mathcal{H}_R)_{a\bar{b}} = -R_{a\bar{b}c\bar{d}}\bar{F}^c F^{\bar{d}}$ , it is easy to see that the length of the tails in  $\mathcal{H}_R$  is intimately related to the curvature of moduli space as measured by

$$\mathcal{R}^2 := R_{a\bar{b}c\bar{d}}R^{a\bar{b}c\bar{d}}, \quad (5.2)$$

which, like the Ricci scalar  $R = -\mathcal{K}^{a\bar{d}}\mathcal{K}^{\bar{b}c}R_{a\bar{b}c\bar{d}}$ , is invariant under the homogeneous rescaling  $\vec{t} \rightarrow \lambda\vec{t}$ . Let us explore this connection in detail. At any given point in moduli space,

we can adopt Kähler normal coordinates in which  $\mathcal{K}_{a\bar{b}} = \delta_{a\bar{b}}$ , in which case the curvature contribution to the Hessian becomes

$$(\mathcal{H}_R)_{a\bar{b}} = -R_{a\bar{b}c\bar{d}}\bar{F}^c F^{\bar{d}} = -R_{a\bar{b}c\bar{d}}\delta^{c\bar{e}}\delta^{f\bar{d}}F_f\bar{F}_{\bar{e}}. \quad (5.3)$$

For fixed  $F^2$ , parametrically large eigenvalues occur when  $F_a$  points in directions of large curvature. In Kähler normal coordinates,  $\mathcal{R}^2$  is just the sum of the squares of the entries in the Riemann curvature tensor, and so the minimum eigenvalues satisfy

$$\lambda_{R,\min} \geq -\mathcal{R}|F|^2. \quad (5.4)$$

The precise alignment of the F-terms with the Riemann tensor required to saturate the bound (5.4) will not occur in generic cases: instead there will be a misalignment by a random rotation. Therefore, generically the eigenvalues of  $\mathcal{H}_R$  will respect the approximate bound

$$\lambda_R \gtrsim -\mathcal{R}|F|^2/h^{1,1}. \quad (5.5)$$

One might think that an even stronger bound may result due to cancellations between opposite-sign terms in the curvature tensor. However, we find empirically that in the deep interior of the Kähler cone, the components  $R_{a\bar{b}c\bar{d}}$  of the Riemann tensor (in the toric basis used throughout this work) are mostly positive.<sup>11</sup> Indeed, if the components of the Riemann tensor had no statistical preference for either sign then an ensemble of Ricci scalars taken from a Calabi-Yau example would be clustered around zero. As shown in figure 14,  $R$  is negative and linearly correlated with  $\mathcal{R}$ , which is a manifestation of the preference of the components of Riemann  $R_{a\bar{b}c\bar{d}}$  to have a positive sign.<sup>12</sup> To understand this finding, we compare to a few simple reference cases. First, the Ricci scalar of a Riemann tensor that has i.i.d. components with zero mean has no preference for either sign, and there is no significant correlation between the invariants: see figure 15a. In the special case of a Kähler manifold for which the metric depends only on the real part of the coordinates, the Ricci scalar has a slight preference to be negative, but there is little correlation between  $\mathcal{R}$  and  $R$  (figure 15b). Finally, in an ensemble of Riemann tensors on a Kähler manifold with i.i.d. *positive* coefficients, the Ricci scalar indeed turns out to be negative, but with only a very slight correlation (figure 15c). Clearly, the structure of the Riemann tensor on a Calabi-Yau Kähler moduli space is more intricate than that of these reference models. The empirical results just described are related to the conjectured bounds on the sectional curvature proposed in [38] (see also [39] for a related proposal and [40] for counterexamples). However, not all examples that we examined have a negative Ricci scalar.

Similar behavior occurs for other threefolds, though the characteristic sizes of the curvatures can be quite different for different threefolds, with no simple scaling with  $h^{1,1}$ . An example Calabi-Yau with  $h^{1,1} = 20$  exhibits smaller curvatures and correspondingly less negative eigenvalues of  $\mathcal{H}_R^{\text{CY}}$ : see figure 16.

<sup>11</sup>Note that this does not violate the antisymmetry of the Riemann tensor, which requires for example that  $R_{a\bar{b}c\bar{d}} = -R_{\bar{b}ac\bar{d}}$ .

<sup>12</sup>That the curvatures are large compared to unity might cause concern since the curvature of moduli

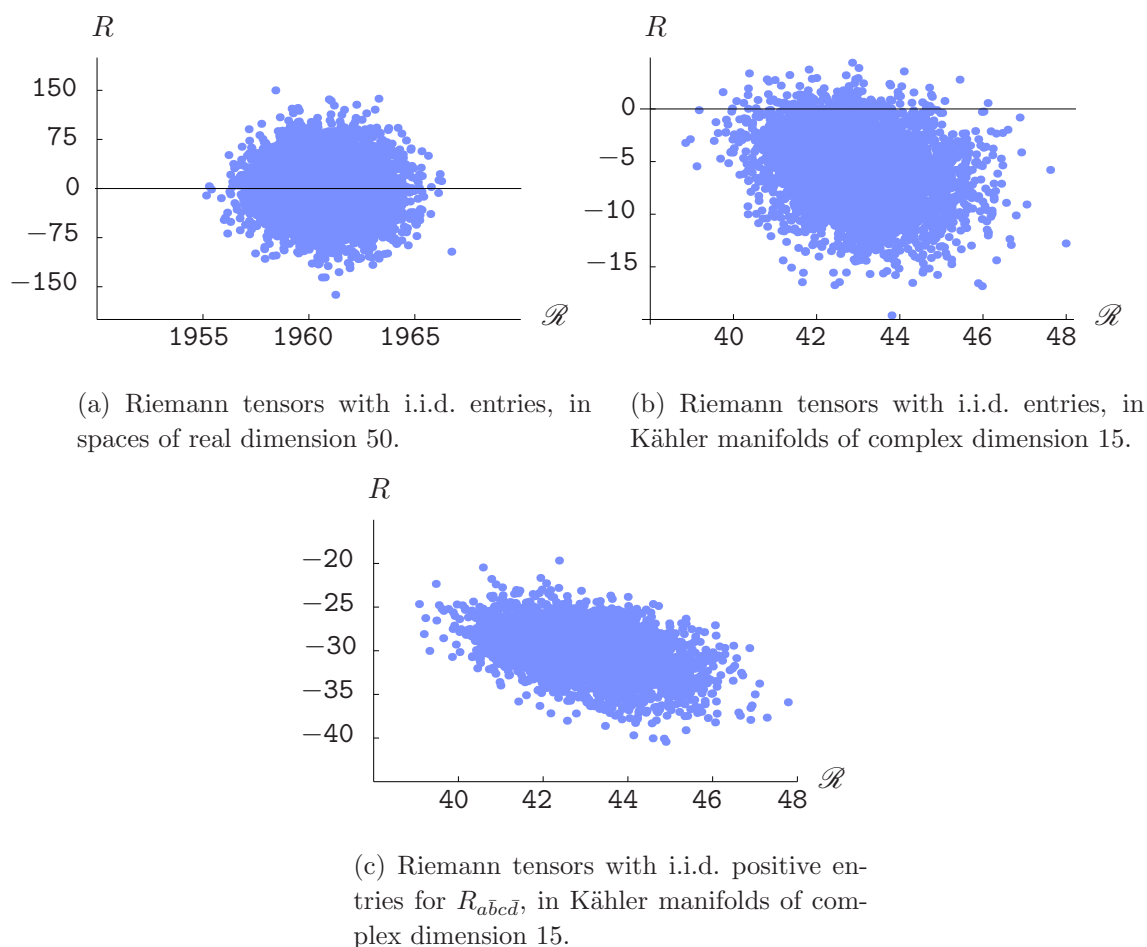

**Figure 14.** Values of  $\mathcal{R} = \left(R_{a\bar{b}c\bar{d}}R^{a\bar{b}c\bar{d}}\right)^{1/2}$  and the Ricci scalar  $R$  taken from an ensemble of points in  $\mathcal{Y}_{25}$ . Contrast figure 15.

The bound (5.5) is simply a scaling result, with the factor of  $h^{1,1}$  determined by modeling a random rotation in a space of dimension  $h^{1,1}$ , and we can only expect it to hold up to an  $\mathcal{O}(1)$  multiplicative factor. Figure 17 compares the minimum eigenvalues of an ensemble of spectra of  $\mathcal{H}_R^{\text{CY}}$ , for a number of threefolds, to the curvature invariants  $\mathcal{R}$ . We observe that 76% of the data satisfy the bound (5.5), while 96% satisfy the weaker bound  $\lambda_{R,\min}^{\text{CY}} < 2\mathcal{R}/h^{1,1}$ .

The scaling of the Hessian eigenvalues with curvature is modulated by the fact that alignment of the F-terms with the directions of maximum curvature is non-generic. It is then interesting to consider the effect that changing the direction of  $\hat{F}_a = F_a/|F|$  has on the tail population. Finding the direction of  $\hat{F}$  that minimizes the smallest eigenvalue is computationally challenging at even modest  $h^{1,1}$ , and so we consider an example with  $h^{1,1} = 4$ . In a particular basis and at a fixed point in moduli space, the maximal sectional curvature is  $R_{1\bar{1}1\bar{1}} \approx 103$ , where we have rotated coordinates so that the direction of largest sectional curvature is the 1 direction. The corresponding minimum eigenvalue of  $\mathcal{H}_R^{\text{CY}}$  is  $\lambda_{R,\min}^{\text{CY}} \approx -200$ . The direction that results in the most negative  $\mathcal{H}_R^{\text{CY}}$ ,  $\hat{F}^{\min}$ , has a large overlap with the 1 direction,  $\hat{F}_1^{\min} \approx 0.8$ . Remaining at the same point in moduli space, we generate an ensemble of Hessians by choosing randomly oriented F-terms. In figure 18 we plot the smallest eigenvalue of  $\mathcal{H}_R^{\text{CY}}$  against the angle between  $\hat{F}$  and  $\hat{F}^{\min}$ . One can see that the orientation of  $\hat{F}$  plays an important role in the population of the tail. For larger  $h^{1,1}$ , finding the direction of  $\hat{F}$  that results in the largest tails towards negativity is computationally challenging, but we observe empirically that when the tails are particularly extensive,  $\hat{F}$  has large overlap with the directions in which the curvature is large.

---

space often diverges near the boundaries of the Kähler cone, where cycles collapse and the supergravity approximation is no longer trustable. However, the points that we consider here are in the bulk of the cone, where  $\alpha'$  corrections are under control.

**Figure 15.** Curvature invariants of random Riemann tensors with increasing amounts of structure. These simple reference models are to be contrasted with the strong correlation exhibited in a Calabi-Yau (figure 14).

**Figure 16.** The spectrum of minimum eigenvalues of  $\mathcal{H}_R^{\text{CY}}$  and the correlation between the Ricci scalar and  $\mathcal{R}$  for a Calabi-Yau with  $h^{1,1} = 20$ . This ensemble consists of 5000 matrices.

**Figure 17.** Comparison of the minimum eigenvalue of  $\mathcal{H}_R^{\text{CY}}$  (in units of  $|F|^2$ ) to the rescaled curvature  $\mathcal{R}/h^{1,1}$ . The data were gathered from a collection of Calabi-Yau threefolds between  $h^{1,1} = 2$  and  $h^{1,1} = 25$ , with five distinct threefolds for each value of  $h^{1,1}$  and about 1000 points in moduli space from each threefold. Each color corresponds to a different value of  $h^{1,1}$ . Well inside the Kähler cone there is typically little variation in curvature, and hence curvature invariants for each Calabi-Yau tend to cluster in vertical stripes. Those points below the line satisfy the bound (5.5).

**Figure 18.** Magnitude of the most negative eigenvalue of  $\mathcal{H}_R^{\text{CY}}$  as a function of the angle of  $\hat{F}$  with respect to the direction that produces the most negative eigenvalue. The eigenvalues are normalized with respect to the most negative eigenvalue obtained. This sample results from a Calabi-Yau with  $h^{1,1} = 4$ .

The maximum value of  $\mathcal{R}$  sets an approximate bound for the minimum eigenvalue of  $\mathcal{H}_R^{\text{CY}}$ . Although the curvature is well behaved, albeit often large, in the interior of the cone, the metric may degenerate and the curvature diverge near the boundary (typically near boundaries that have codimension greater than 1). The boundaries of the Kähler cone are marked by the collapse of one or more 2-cycles where corrections to the leading-order Kähler potential become important, and so we have remained away from the boundaries in all of our analysis thus far. However, to expose the relationships between curvature and eigenvalue hierarchies derived from the leading-order Kähler potential, it is useful to approach the boundaries, with the understanding that in actual string compactifications there would be large corrections to these results.

We illustrate this in an example with  $h^{1,1} = 15$ , approaching a codimension two boundary of the Kähler cone where  $A_{ab} = \partial t_a / \partial \tau^b$  degenerates. The distance to the wall is parameterized by  $t$ , which measures the volume of the two 2-cycles that are shrinking. In figure 19a we demonstrate the relationship between  $\mathcal{R}$  and  $t$ : the curvature diverges as we approach this boundary. A related effect is that  $A^{-1}$  develops a zero eigenvalue and consequently, via (3.12a), one of the eigenvalues of the metric  $\mathcal{K}_{a\bar{b}}$  diverges (figure 19b). To explore the behavior of the curvature Hessian, at each point in moduli space we generate  $10^5$  random F-terms, and calculate the eigenvalues of  $\mathcal{H}_R^{\text{CY}}$ . In figure 19c, we demonstrate the correlation between the minimum eigenvalue and  $\mathcal{R}$ : as  $t \rightarrow 0$  and  $\mathcal{R}$  grows, the length of the tail in  $\mathcal{H}_R^{\text{CY}}$  also grows.

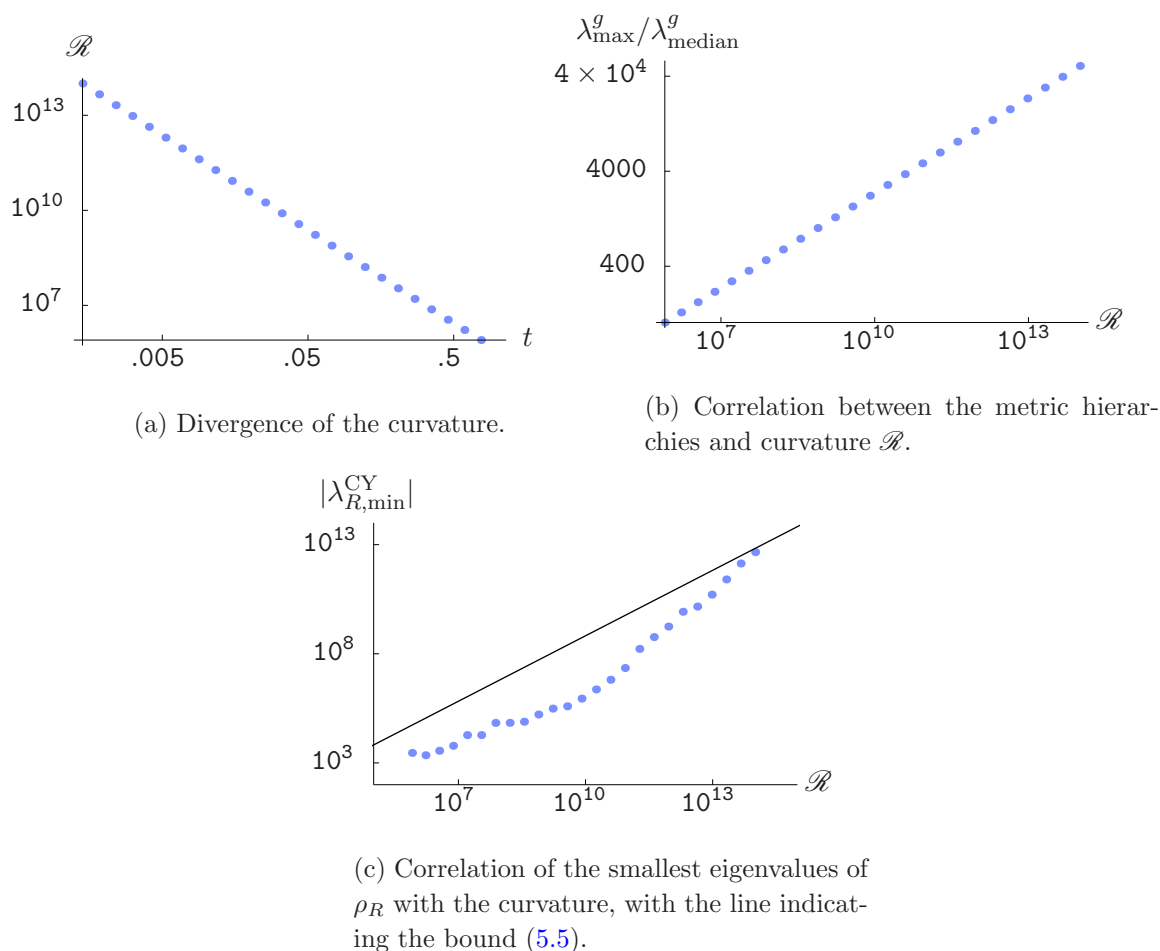

## 5.5 Implications for stability

The presence of heavy tails in the distribution of negative eigenvalues of the curvature contribution  $\mathcal{H}_R^{\text{CY}}$  to the total Hessian  $\mathcal{H}$  may have considerable impact on the probability  $P_+$  that a Hessian drawn from the ensemble has only positive eigenvalues. In this section we will comment briefly on the effect of heavy tails on  $P_+$ .

Direct study of  $P_+$  requires a fully-specified stochastic model for the superpotential and its derivatives. While in a characterization of  $\mathcal{H}_R$  the details of the superpotential model have little impact, in the full Hessian  $\mathcal{H}$  they can be determinative. To apply the i.i.d. model of  $W$  used in [7, 16], it is necessary to fix a physically meaningful ambiguity, namely the relative r.m.s. sizes of  $F_a$ ,  $Z_{ab}$ , and  $U_{abc}$ . As explained in this context in [16], the relative magnitudes of the F-terms and of the supersymmetric masses encoded in  $Z_{ab}$  reflect the strength of supersymmetry breaking, and the prevalence of corresponding instabilities. Modeling supersymmetry breaking in this manner necessarily introduces a large degree of model-dependence, and we defer a detailed analysis to future work.

Even without modeling the non-curvature Hessian  $\mathcal{H} - \mathcal{H}_R$ , we can draw a few qualitative conclusions about the impact of the heavy tails toward negativity in  $\mathcal{H}_R$ . We consider the fraction of eigenvalues that are negative in our ensemble of curvature Hessians  $\mathcal{H}_R$ , and compare this to the fraction of negative eigenvalues in the i.i.d. Wigner+Wishart model discussed in section 2.2, i.e. for the null hypothesis (1.3).

Focusing first on  $\mathcal{V}_{25}$ , the mean fraction of negative eigenvalues is 43%, which is significantly higher than the 14% fraction we find in Wigner+Wishart matrices of the same size. However, the distribution in the case of  $\mathcal{V}_{25}$  has a wider spread, with a standard

**Figure 19.** Behavior of the curvature, metric eigenvalues, and curvature Hessian eigenvalues as one approaches a particular boundary of the Kähler cone by taking  $t \rightarrow 0$ . The hierarchies in the metric eigenvalues are measured by comparing the largest eigenvalue to the median eigenvalue. Corrections to the leading-order Kähler potential are large in this regime, as explained in the main text.

deviation of 2.5% for the Calabi-Yau data and 1.2% for the Wigner+Wishart matrices (see figure 20). For a more meaningful comparison we therefore rescale the mean fraction of negative eigenvalues by the standard deviation of the corresponding distribution. Repeating this analysis for several different threefolds at different values of  $h^{1,1}$  yields figure 21. We find that the rescaled fraction of negative eigenvalues generally increases more quickly with  $h^{1,1}$  in the threefold examples than it does in Wigner+Wishart or Wigner reference models. Although this proxy is suggestive of decreased metastability, a more precise result requires detailed study of the full Hessian that incorporates superpotential data.

## 5.6 Other string theories

In all of the above, we focused on the properties of the Hessian on the Kähler moduli space of O3/O7 orientifolds of a Calabi-Yau threefold, in which the Kähler coordinates are complexifications of 4-cycle volumes. In other corners of the landscape, including the heterotic

**Figure 20.** Distribution of the fraction of negative eigenvalues in the curvature Hessian. The Hessians are taken from ensembles of  $\mathcal{H}_R^{\text{CY}}$  for  $\mathcal{Y}_{25}$  and of  $\mathcal{H}_R^{\text{WW}}$  for 25 complex scalar fields (1.3). For the Calabi-Yau data, the mean and standard deviation of this distribution are 43% and 1.2%, while for the WW distribution, the mean and standard deviation are 2.5% and 1.2%.

**Figure 21.** A proposed proxy for the probability of large fluctuations of  $\mathcal{H}_R$  in the direction of positivity: the expectation value of the fraction of negative eigenvalues divided by the standard deviation of the distribution of this fraction. The growth of this quantity with  $h^{1,1}$  should trace the growth of instabilities with  $h^{1,1}$ . Shown are results for Wigner matrices ( $\blacktriangle$ ), the Wigner+Wishart model ( $\blacksquare$ ) and Calabi-Yau examples ( $\bullet$ ). The Wigner and Wigner+Wishart data were gathered from ensembles of 5000 matrices at each point, while the Calabi-Yau data were gathered from ensembles of 5 threefolds at each  $h^{1,1}$  with 1000 Hessians from each threefold.

**Figure 22.** The spectrum of an ensemble of 5000 curvature Hessians  $\mathcal{H}_R^{\text{CY}'}$  for  $\mathcal{Y}_{25}$ , with the Kähler coordinates that arise in compactification of the heterotic string, O5/O9 projections of type IIB, or O6 projections of type IIA.

string, O5/O9 projections of type IIB, and O6 projections of type IIA, the complexified Kähler moduli are complexifications of 2-cycle volumes,  $J + i B_2 = \varrho^i \omega_i$  (in O5/O9 projections,  $C_2$  rather than  $B_2$  is used). Our methods readily apply to these constructions, and it is interesting to compare the spectra shown in section 5 to these cases. We denote the resulting Hessians by  $\mathcal{H}_R^{\text{CY}'}$ . The eigenvalue spectrum of an ensemble of matrices  $\mathcal{H}_R^{\text{CY}'}$  for  $\mathcal{Y}_{25}$  is shown in figure 22. Just as in the O3/O7 projection of type IIB, we find extended tails. One noteworthy difference from the O3/O7 projection is that the Ricci scalar in the case of  $\mathcal{H}_R^{\text{CY}'}$  is typically positive, and  $\mathcal{H}_R^{\text{CY}'}$  exhibits corresponding positive tails. We defer a more complete consideration of these classes of compactifications to future work.

## 6 Reference models

In the previous sections, we identified key statistical properties of the Kähler metrics and curvature Hessians  $\mathcal{H}_R$  arising in compactifications on (orientifolds of) explicit Calabi-Yau

hypersurfaces in toric varieties. The presence of extensive tails — toward positivity for  $\mathcal{K}_{a\bar{b}}$ , and in both directions for  $\mathcal{H}_R^{\text{CY}}$  — is the most striking feature of these ensembles.

Our findings establish that the i.i.d. Wigner+Wishart model (1.3) for  $\mathcal{H}_R$  proposed in [16] must be modified in order to reflect the properties of actual Calabi-Yau compactifications. The i.i.d. model, however, does have the important virtues of simplicity and extremely low computational cost in comparison to the analysis described in this paper. It would be instructive to identify a stochastic model that shares some of the simplicity of the i.i.d. Wigner+Wishart model, but more accurately models the geometry of Calabi-Yau moduli spaces. In this section we will describe several candidate models for  $\mathcal{H}_R$ , among which the Bergman metric discussed in section 6.3 has the most qualitative success, though in its simplest form it lacks the heavy tails of the Calabi-Yau spectrum.

### 6.1 Random intersection numbers

A central result of this paper is that correlations between the various contributions to the Hessian will impact the features of the eigenvalue spectrum. Although we focused on the particular example of O3/O7 orientifolds of Calabi-Yau manifolds, correlations should be a universal feature, and further elucidation of their effect could be obtained by a study of i.i.d. Kähler potentials. One could hope to model the Kähler potential as

$$\mathcal{K} = -2 \log \left( \frac{1}{3!} c^{abc} t_a t_b t_c \right), \quad (6.1)$$

where  $c^{abc}$  is a totally symmetric i.i.d. tensor. This approach is immediately problematic: for almost all choices of  $c^{abc}$ , and for almost all points in the space spanned by  $t_a$ , the metric following from (6.1) has negative eigenvalues. Finding the interior of the Kähler cone numerically is then very difficult. In fact there is no guarantee that the Kähler cone will not be empty for a generic set of random intersection numbers.<sup>13</sup>

### 6.2 Random positive Riemann curvature

The components  $R_{a\bar{b}c\bar{d}}$  of the Riemann tensors on the Kähler moduli spaces that we study are nearly always positive. An ad hoc modification of the i.i.d. approach would be to impose positivity on the i.i.d. components. We accomplish this in a very crude way by generating an ensemble of Riemann tensors by adding i.i.d.  $\mathcal{K}^{(3)}$  and  $\mathcal{K}^{(4)}$  contributions and then taking the absolute values of the resulting tensor components. This prescription yields an ensemble of matrices  $\mathcal{H}_R^{\text{i.i.d.}+}$  which manifest an increased correlation between the curvature tensors (figure 15c). Correspondingly, the curvature Hessian spectrum displays a tail towards negativity as shown in figure 23. However, these features are not as pronounced as in the Calabi-Yau case.

### 6.3 Random Bergman metrics

A construction that allows for a definition of a random Kähler potential is the Bergman metric, which comes from the embedding of compact Kähler manifolds into projective space

<sup>13</sup>Further refinement could be obtained by incorporating the consistency requirements for the intersection numbers on a Calabi-Yau discussed in [41].

**Figure 23.** The spectrum of  $\mathcal{H}_R^{i.i.d.+}$ , in which  $R_{a\bar{b}c\bar{d}}$  are taken to be i.i.d. and positive. Here  $h^{1,1} = 15$ , and the ensemble consists of 5000 matrices.

along the lines of Kodaira.<sup>14</sup> In practice, the Bergman metric on a Kähler manifold with coordinates  $z^i$  is specified by the Kähler potential:

$$\mathcal{K}(z, \bar{z}) = \frac{1}{k} \log f(z, \bar{z}), \quad f(z, \bar{z}) := \bar{s}_\alpha(\bar{z}) P_{\alpha\beta} s_\beta(z), \quad (6.2)$$

in which  $\{s_\alpha(z)\}$  is a basis of polynomials of degree  $\leq k$  and  $P$  is a positive-definite Hermitian matrix.  $f$  is called the Bergman kernel. A particular Bergman metric is defined by a choice of positive-definite matrix  $P_{\alpha\beta}$ , and by taking the entries of this matrix to be i.i.d., one can construct a *random Bergman metric*, in the spirit of [9–11].

One might be tempted to use (6.2) to construct an ensemble of metrics that scale homogeneously under  $z^i \rightarrow \lambda z^i$ , and thereby model the homogeneous metrics on the moduli space of a Calabi-Yau. However, positive-definiteness of the Bergman metric is only guaranteed when  $P$  is positive-definite, and in particular is not degenerate. Indeed, if  $P$  is such that  $f$  is a homogeneous function under  $z^i \rightarrow \lambda z^i$ , then the resulting metric is degenerate.<sup>15</sup> More generally, if  $P$  were not positive-definite, then the metric would only be positive-definite in certain regions in moduli space, and finding such regions is computationally difficult when the dimension of the space is large.

One way to study a Bergman metric is to fix the matrix  $P$ , and then scan over a neighborhood in the coordinates  $z^i$ . However, when  $z^i \bar{z}^{\bar{i}}$  is large and  $k$  is finite, the kernel is dominated by the largest-power monomials in the basis, and so  $f$  is well-approximated by a homogeneous function of degree  $2k$ . As discussed above, homogeneous kernels are degenerate, and so the metric is guaranteed to have singularities for sufficiently large  $z$ .

An alternative to exploring a small region with a fixed kernel is to generate a new  $P_{\alpha\beta}$  at each point in moduli space, and then redefine the coordinates such that the point under consideration is  $z^i = 0$ . The philosophy is quite similar to the i.i.d. approach in that we assume that we work with an ensemble of Hessians generated at points in moduli space that

<sup>14</sup>See [42] for a mathematical review.

<sup>15</sup>The argument is very similar to the argument used in section 3.3 to argue for the negativity of  $\mathcal{H}_R$  — for a homogeneous kernel, contraction of the metric with  $z^i$  shows that the metric is degenerate.

**Figure 24.** Eigenvalue spectra for the  $\mathcal{K}^{(3)}$  and  $\mathcal{K}^{(4)}$  contributions to the Hessian in the case of Bergman metrics. Each ensemble consists of 1000  $20 \times 20$  matrices.

have a separation that is large in comparison to the correlation length of  $P$ . Therefore, as in the i.i.d. approach, we lose information about correlations between Hessians at different points but retain correlations between the various derivatives of the Kähler potential at each point.<sup>16</sup> Since calculation of the Riemann tensor of a Kähler metric requires no more than two holomorphic or anti-holomorphic derivatives (see (2.6)) and we are evaluating all tensors at  $z = 0$ , we can take the  $s_\alpha$  to be quadratic polynomials.

We now consider an ensemble of Bergman metrics as described above, taking  $P$  to be a random Wishart matrix. The Riemann tensor can be calculated entirely in terms of  $P_{\alpha\beta}$ . In order to construct the associated contribution to the Hessian  $\mathcal{H}_R^B$  we need to include F-terms. As in the O3/O7 case, we take the F-terms to be

$$F_a \in F \Omega(0, \sigma), \quad \sigma = 1/\sqrt{N}, \quad (6.3)$$

and then report on the distribution of eigenvalues of the canonically-normalized and rescaled curvature Hessian (cf. (4.6)).

The spectrum of eigenvalues of  $\mathcal{H}_R^B$  has qualitative features that resemble those of the Calabi-Yau hypersurface examples. In particular, the log-type Kähler potential leads to correlations between  $\mathcal{H}_{\mathcal{K}^{(3)}}^B$  and  $\mathcal{H}_{\mathcal{K}^{(4)}}^B$ , as shown in figure 24, that are very similar to the correlations shown in figure 10. In addition, both the spectrum of  $\mathcal{H}_R^B$  and the correlation between curvature invariants shown in figure 25 mirror the Calabi-Yau case. Since the curvature invariants are small, the tails are not as extensive as in the Calabi-Yau case. Indeed, repeating the analysis in section 5.3, we find no significant evidence for the tails to be heavy.<sup>17</sup>

The Bergman metric has features that make it appealing as a model for moduli space metrics: it incorporates the correlations between  $\mathcal{K}_{(3)}$  and  $\mathcal{K}_{(4)}$ , and appears to have similar relationships between  $R$  and  $\mathcal{R}$  as in the Calabi-Yau case. However, although fluctuations

<sup>16</sup>Correlations between different points could be incorporated, at least in a statistical sense, by implementing the techniques of [17].

<sup>17</sup>If one instead takes the entries of the  $P_{\alpha\beta}$  appearing in the Bergman Kähler potential (6.2) to be drawn from a heavy-tailed distribution, the resulting metric spectra can have heavy tails.

**Figure 25.** Distribution of eigenvalues for  $\mathcal{H}_R^B$  at  $h^{1,1} = 20$ , and the correlation between the curvature invariants.

to positivity in  $\mathcal{H}_R^B$  are rare, they are not prevented from occurring. Furthermore, at large “volume”  $f$ , where the argument of the logarithmic Kähler potential is well-modeled by a degree-three homogeneous function, one should expect a non-positive spectrum of  $\mathcal{H}_R$ . Said differently, it is not clear how to connect the preferred coordinates in terms of which the volume is homogeneous to the coordinates used in the Bergman metric.

## 7 Spectra of axion decay constants

A significant application of our results is to the problem of determining axion decay constants. The axion decay constant spectrum is relevant for a wide range of questions, including analysis of the “axiverse” proposed in [43], the study of axion dark matter, late time decays, etc. For the particular purpose of developing models of inflation in string theory, it is important to understand whether axion decay constants can reach or exceed the Planck scale,  $f \gtrsim M_{\text{pl}}$ . While axion decay constants in string theory have been the subject of intensive study (see [21, 22] and the overview in [44]), most results to date have involved either single axions; pairs of axions; or, in systems with  $N \gg 1$  axions, “democratic” estimates in which the  $N$  decay constants are taken to be essentially comparable and uncorrelated [45, 46]. Here we initiate a more systematic study of the *statistics* of axion decay constants, incorporating the critical phenomenon of eigenvalue repulsion.

In a compactification of type IIB string theory on a Calabi-Yau orientifold with O3-plane and O7-plane fixed loci, the intersection numbers determine the classical effective action for the Kähler moduli  $\rho^a = \tau^a + i c^a$ , including in particular the axions<sup>18</sup>

$$c^a = \int_{D^a} C_4. \quad (7.1)$$

<sup>18</sup>The same data determine the classical action for axionic fields descending from  $C_2$  and  $B_2$ , in compactifications with  $h_-^{1,1} > 0$ , but for simplicity we will describe only the case  $h_-^{1,1} = 0$ .

The kinetic term for these axions is given by the Kähler metric  $\mathcal{K}_{a\bar{b}}$  (3.12a): taking the  $\tau^a$  to be constants, the low-energy Lagrangian includes

$$\mathcal{L} \supset \mathcal{K}_{a\bar{b}}(\tau^c) \partial c^a \partial c^b - \sum_a \Lambda_a^4(\tau^c) \cos(c_a/\zeta_a). \quad (7.2)$$

where the potential term represents instanton contributions that break the perturbative shift symmetries  $c_a \rightarrow c_a + \text{const.}$  to discrete shifts  $c_a \rightarrow c_a + 2\pi\zeta_a$ . In the absence of a preferred basis for the Kähler moduli space, one could rescale the  $\rho_a$  to arrange that each of the  $c_a$  has period  $2\pi$ , i.e. setting  $\zeta_a \rightarrow 1$ , but we will not do so here: instead, the metric  $\mathcal{K}_{a\bar{b}}(\tau^c)$  is taken to be expressed in the basis used throughout this work.

Determining the decay constant  $f$  in a model with  $h_+^{1,1} = 1$  and a corresponding single axion  $c$  is straightforward: defining  $\mathcal{K}_{c\bar{c}} = f^2$ , the Lagrangian takes the form

$$\mathcal{L} = \frac{1}{2} f^2 (\partial c)^2 - \Lambda_c^4 \cos(c/\zeta). \quad (7.3)$$

so that by defining  $\phi = fc$  we arrive at

$$\mathcal{L} = \frac{1}{2} (\partial \phi)^2 - \Lambda_c^4 \cos\left(\frac{\phi}{f\zeta}\right). \quad (7.4)$$

The periodicity of the canonically-normalized field  $\phi$  is then  $2\pi f\zeta$ . As explained in [47], in generalizing this result to multiple axions one must carefully account for kinetic mixing, i.e. off-diagonal terms  $\mathcal{K}_{a\bar{b}}$ ,  $b \neq a$ : the orthogonal rotation that diagonalizes  $\mathcal{K}_{a\bar{b}}$  does not preserve the form of the potential in (7.2), in which each field appears in only a single cosine term in the potential. Nevertheless, we will define the decay constants in an  $N$ -axion system to be the (positive square roots of the) eigenvalues  $\lambda_a$  of the Kähler metric:  $f_a = \sqrt{\lambda_a}$ . We will order the eigenvalues for convenience,  $f_1 \leq f_2 \leq \dots \leq f_N$ , with  $N = h_+^{1,1}$ .

A natural goal would be to derive a matrix model for the Kähler metric analogous to the Wigner+Wishart+Wishart matrix model for the Hessian obtained in [16], and to obtain analytic results for the eigenvalue spectrum, and hence for the spectrum of decay constants. This problem is beyond the scope of the present work, and we limit ourselves to conclusions that can be extracted from the ensemble of Kähler metrics presented in section 5.

For the purpose of characterizing the spectra of axion decay constants, the principal qualitative lesson of our analysis is that the eigenvalue spectrum of the Kähler metric displays a pronounced tail to the right of the median. Because the extreme eigenvalues are very different from typical eigenvalues, a computation (or an estimate of the moduli dependence of) an *individual* decay constant  $f_*$ , along the lines of [21, 22], does not directly constrain the full spectrum. In particular, depending on whether  $f_*$  is a typical member of the spectrum, or belongs to the left or right tail, the remaining decay constants may extend over several decades in either direction.

Large outliers, i.e. decay constants belonging to the right tail of the spectrum, provide the tantalizing prospect of achieving super-Planckian decay constants in a compactification in which all parametric expansions are under good control, and *typical* decay constants are very small in Planck units. However, although super-Planckian effective decay constants

appear possible via collective excitations in systems with  $N \gg 1$  axions [45] (and can be enlarged via kinetic alignment as in [47]) or via decay constant alignment [48] of two axions, in neither of these cases is a super-Planckian eigenvalue of the Kähler metric responsible for the large decay constant. In generic examples in the interior of the Kähler cone, the parametric bound  $f \lesssim 1$  of [21] appears to apply to the maximal eigenvalues  $f_N$  in our ensemble, not to the typical eigenvalues. Identifying non-generic exceptions with super-Planckian decay constants, while ensuring the validity of the  $\alpha'$  expansion, is an intriguing problem for future work.

## 8 Conclusions

The primary results of this work are statistical models for the metric on Kähler moduli space in string compactifications on Calabi-Yau hypersurfaces in toric varieties, and for the corresponding Riemann curvature contribution  $\mathcal{H}_R$  to the Hessian matrix.<sup>19</sup> Our starting point was the assumption made in [16] (and implicitly in much earlier work) that for the purpose of studying vacuum statistics, the derivatives of  $\mathcal{K}$  may be taken to be independent and identically distributed random variables. At the level of random matrix models, assuming i.i.d. entries allows one to model  $\mathcal{H}_R$  as the sum of a Wishart matrix and a Wigner matrix [16],

$$\mathcal{H}_R^{\text{i.i.d.}} \approx \mathcal{H}_R^{\text{WW}}, \quad (8.1)$$

for which the eigenvalue spectrum can be computed analytically, and the fluctuation probabilities can be obtained. In this work we did not take the derivatives of  $\mathcal{K}$  to be independent, but instead accounted for the correlations that follow from the well-known form of the classical Kähler potential,

$$\mathcal{K} = -2 \log \mathcal{V} = -2 \log \left( \frac{1}{3!} \kappa^{abc} t_a t_b t_c \right). \quad (8.2)$$

One key finding at this level is that although  $\mathcal{H}_R^{\text{WW}}$  has a nonvanishing (albeit small) probability to fluctuate to positivity,  $\mathcal{H}_R^{\text{CY}}$  is *necessarily non-positive*, with at least one negative eigenvalue. Thus, incorporating the correlations in  $\mathcal{K}$  reduces the probability of metastability.<sup>20</sup>

The non-positivity of  $\mathcal{H}_R^{\text{CY}}$  follows directly from the form (8.2), combined with the fact that  $\mathcal{V}$  is a homogeneous function of the Kähler moduli. No knowledge of the intersection numbers  $c^{ijk}$  is required. On the other hand, bounding a single eigenvalue is less informative than a statistical description of the entire eigenvalue spectrum, which does require additional geometric input.

To go further, we examined the actual form of  $\mathcal{H}_R^{\text{CY}}$  in an ensemble of compactifications on Calabi-Yau hypersurfaces in toric varieties. We found that  $\mathcal{H}_R^{\text{CY}}$  is strikingly different from  $\mathcal{H}_R^{\text{WW}}$ : in particular, the eigenvalue spectrum of  $\mathcal{H}_R^{\text{CY}}$  displays *heavy tails* toward negative eigenvalues (see figures 7, 8, and 9a), in contrast to the well-localized spectrum

<sup>19</sup>Our most significant results were obtained for O3/O7 orientifolds of type IIB, but other string theories were considered in section 5.6.

<sup>20</sup>See [49] for a study of the incidence of instabilities in a related class of geometries.

of  $\mathcal{H}_R^{\text{WW}}$  (figures 2b and 9b). We showed that the tails in  $\mathcal{H}_R^{\text{CY}}$  are closely correlated to heavy tails in the eigenvalues of the Kähler metric<sup>21</sup> (figure 5), which in turn are tied to hierarchies of 2-cycle volumes (figure 19). Correspondingly, the tails in  $\mathcal{H}_R^{\text{CY}}$  are largest at points in moduli space that are close to a wall of the Kähler cone. However, we argued that the tails are not caused by failure of the  $\alpha'$  expansion: heavy tails are present when there are modest hierarchies in cycle volumes, even if all cycles are large in string units.

Our results shed light on the characteristic properties of mass matrices and metrics on moduli space in Calabi-Yau compactifications of string theory. We discussed two significant implications: first, the heavy tail toward negativity in  $\mathcal{H}_R^{\text{CY}}$  very plausibly leads to an increased incidence of instabilities in comparison to the reference model  $\mathcal{H}_R^{\text{WW}}$ . Second, the heavy tails in the eigenvalues of the Kähler metric imply that in Calabi-Yau compactifications with many axions, the axion decay constants are hierarchically separated, with the largest eigenvalue orders of magnitude larger than the smallest eigenvalue.

Exploring the consequences of these findings, as well as extending our results to broader classes of compactifications, are important problems for the future.

## Acknowledgments

We are grateful to Michael Douglas, Juan Maldacena, and Itamar Yaakov for comments that provided inspiration for a portion of this work. We thank Lara Anderson, Thomas Bachlechner, James Gray, Jim Halverson, Ben Heidenreich, Sheldon Katz, Dave Morrison, Tom Rudelius, Jim Sethna, Gary Shiu, John Stout, and Timm Wrase for related discussions. We are especially indebted to Julia Goodrich for technical assistance. This work was supported by NSF grant PHY-0757868.

## A Toric geometry

In this appendix we provide a brief review of the aspects of toric varieties and Calabi-Yau hypersurfaces that are used in our work. For more complete expositions of toric varieties see [4, 50–55].

A physical definition of a toric variety is as the moduli space of a 2d  $\mathcal{N} = (2, 2)$  field theory. In general, the moduli space of such a theory is a Kähler manifold. To specialize to a toric variety, we consider a  $U(1)^s$  gauge group and  $r$  chiral superfields  $X^i$ , where the charge of the  $i$ th chiral superfield under the  $a$ th  $U(1)$  factor is  $Q_i^a$ . Each  $U(1)$  factor has a Fayet-Iliopoulos term  $\xi^a$ , so that the D-flatness condition is

$$\sum_i Q_i^a |X^i|^2 = \xi^a. \quad (\text{A.1})$$

The resulting moduli space is a toric variety.

A useful collection of divisors are the toric divisors  $\hat{T}^i$  defined by  $X^i = 0$ . Because of the  $U(1)^s$  gauge symmetry, the coordinates  $X^i$  on  $\mathbb{C}^r$ , known as homogeneous coordinates,

---

<sup>21</sup>Recall that we worked in a fixed coordinate system defined by a specified basis of cycles, so the eigenvalues of the metric are meaningful.

are not functions on the toric variety. On the other hand, gauge-invariant combinations of the  $X^i$  are well-defined functions, and the corresponding vanishing loci are homologically trivial. Thus, not all of the toric divisors  $\hat{T}^i$  are homologically independent, and indeed the number of independent divisors is equal to the rank of the gauge group. We will use  $\{\hat{D}^i\}$  to refer to a set of independent toric divisors. To our knowledge, there is no natural or canonical basis choice for the  $\hat{D}^i$ , and we work in the bases adopted in the software packages that we use. The intersection numbers among the toric divisors  $\hat{T}^i$  (and therefore the independent divisors  $\hat{D}^i$ ) can be calculated by simultaneously solving  $X^i = 0$  subject to the D-term constraint.

The Chern class of a toric variety  $V$  is

$$c(V) = \prod_{i=1}^r (1 + [\hat{T}^i]), \quad (\text{A.2})$$

where  $[\hat{T}]$  denotes the Poincaré dual of  $\hat{T}$ . From the adjunction formula, it follows that the hypersurface

$$S = \sum_i \hat{T}^i \quad (\text{A.3})$$

has vanishing first Chern class, and so is Calabi-Yau. Calabi-Yau hypersurfaces of the form (A.3) are the only Calabi-Yau manifolds considered in our analysis.

The intersections of toric divisors  $\hat{D}^a$  with the Calabi-Yau hypersurface furnish divisors of the hypersurface. When all of the divisors of the Calabi-Yau are inherited from the ambient toric variety in this way, the polytope is said to be *favorable*, and we limit our analysis to such cases. One can easily check whether a polytope is favorable by calculating  $h^{1,1}$  from the toric data [56].

The classes of holomorphic curves in an  $n$ -dimensional toric variety form a cone called the Mori cone, which can be determined by considering the intersections of  $(n-1)$  toric divisors. The Mori cone is generated by a set of curves  $\hat{C}_i$ , and the intersections between the divisors of the toric variety and these curves are given by the charge matrix

$$Q_i^a = \hat{C}_i \cdot \hat{D}^a. \quad (\text{A.4})$$

Note that the Mori cone of the Calabi-Yau is not in general the same as the Mori cone of the ambient toric variety. For example, if a curve of the ambient variety does not intersect the Calabi-Yau hypersurface, then the curve may be safely taken to zero volume and even be allowed to flop. However, positivity of curves of the ambient space implies positivity of the curves of the hypersurface.<sup>22</sup>

The data of a compact toric variety can be encoded by a polytope, which is a higher-dimensional generalization of a polyhedron. We will consider  $n$ -dimensional polytopes  $\Delta$  that are *reflexive*, meaning that the only point of  $\mathbb{Z}^n$  that is in the interior of  $\Delta$  is the origin, and that  $\Delta$  can be expressed as an intersection of half-spaces

$$\Delta = \bigcap_F \{ \mathbf{m} \in \mathbb{R}^n \mid \mathbf{m} \cdot \mathbf{n}_F \geq -1 \}, \quad (\text{A.5})$$

---

<sup>22</sup>See [57] for more work on determining the Mori cone of the hypersurface itself.

where  $F$  denotes a codimension-1 face of  $\Delta$ , and  $\mathbf{n}_F$  is the shortest vector in  $\mathbb{Z}^n$  that is an inward-facing normal to  $F$ . Given a polytope  $\Delta$ , its dual polytope  $\Delta^\circ$  is defined by taking the points  $\mathbf{n}_F$  as the vertices of  $\Delta^\circ$ . When  $\Delta$  is reflexive,  $\Delta^\circ$  is reflexive.

The next step is to triangulate  $\Delta^\circ$ : that is, we divide  $\Delta^\circ$  into simplices. In particular, we consider triangulations of  $\Delta^\circ$  that are *star*, which means that all simplices share one common point as a vertex. For our purposes this point will be the origin, as each simplex defines a cone with the tip being the origin, and one can form a fan by pasting together such cones. To each line segment  $\mathbf{v}^i$  that connects to the origin, we associate one of the variables  $X^i$ . The  $\mathbf{v}^i$  satisfy a set of linear relations,

$$Q_i^a \mathbf{v}^i = 0, \quad (\text{A.6})$$

which give the charge matrices. Note that there are multiple ways of triangulating a polytope, and thus a polytope does not define a unique toric variety. However, the various varieties are related to each other via blowups and blow-downs.

A necessary condition for a non-empty Kähler cone is that the triangulation is *regular*, meaning that the triangulation is a projection of the bottom part of an  $(n+1)$ -dimensional polytope. More precisely, let  $\{\mathbf{m}_k\}$  be the points of the triangulation of  $\Delta^\circ$ . Then the triangulation is regular if there exists an  $(n+1)$ -dimensional polytope  $\Xi$  containing points  $(\mathbf{m}_k, \lambda_k)$  whose inward-facing normals have positive  $(n+1)$ -dimensional components.

Toric varieties are generally singular, but when the triangulation is *maximal*, meaning that every point in  $\mathbb{Z}^n$  that is in  $\Delta^\circ$  is a vertex of a simplex of the triangulation, then the variety becomes smooth. In such a situation, the Calabi-Yau hypersurface will also be smooth. In fact, total smoothness of the variety is not necessary to ensure smoothness of a generic hypersurface: at generic points in the complex structure moduli space of the Calabi-Yau, the hypersurface will miss pointlike singularities of the ambient variety. Thus, our triangulations need not include the points in the interior of codimension-1 faces (facets) of the polytope. We are therefore led to consider complete regular star triangulations of favorable reflexive polytopes, ignoring points interior to facets.

## B Triangulation algorithm

A common way to obtain complete, regular, star triangulations is to calculate all complete, regular triangulations and then select those that are star. This is extremely inefficient if one is interested only in star triangulations. In order to directly obtain triangulations that are star, we recall that by definition, each point in a star triangulation is connected to the origin by a line. One can therefore obtain a complete star triangulation by triangulating each of the facets, drawing a line from the origin to each point on the facets, and enforcing that the triangulations of each facet agree on the overlaps of facets.

The resulting triangulation is automatically maximal and star, but it is still necessary to check for regularity. We present our algorithm below, illustrated for concreteness in the case of a polytope  $P$  with four facets,  $F_a, F_b, F_c$ , and  $F_d$ :

1. Find all regular, complete triangulations of each facet. We obtained these triangulations from TOPCOM [58], using Sage as an interface.

**Figure 26.** Facet 1 and Facet 2 are three-dimensional facets of a four-dimensional polytope. The facets overlap along the surface  $\langle abcd \rangle$ .

2. Organize the facets into pairs, such that each facet in a pair has nonzero intersection with its partner. If facets  $F_a$  and  $F_b$  intersect, and facets  $F_c$  and  $F_d$  intersect, create the pairs  $(F_a, F_b)$  and  $(F_c, F_d)$ .
3. For each pair of facets, compare the triangulations of each member of the pair on the intersection, retaining only those triangulations that are regular and agree on the overlap. That is, let  $S$  be the overlap of the facets  $F_a$  and  $F_b$ , and let  $\Delta_a$  and  $\Delta_b$  be triangulations of facets  $F_a$  and  $F_b$ , respectively. Determine whether  $\Delta_a$  and  $\Delta_b$  agree on  $S$ , and whether  $\Delta_a \cup \Delta_b := \Delta_{ab}$  is regular (including the lines drawn to the origin). Retain  $\Delta_{ab}$  if and only if it is regular. Repeat this process for all other pairs of facets.
4. Combine  $F_a$  and  $F_b$  into a single *intermediate polytope*  $F_{ab}$  with regular triangulations  $\{\Delta_{ab}^i\}$ , and combine  $F_c$  and  $F_d$  into an intermediate polytope  $F_{cd}$  with regular triangulations  $\{\Delta_{cd}^{i'}\}$ . Do the same for all other pairs of facets.
5. Repeat steps 2, 3, and 4 for the new pairs, such as  $(F_{ab}, F_{cd})$ , until the full polytope is triangulated.

The above method yields all complete, regular, star triangulations of the polytope  $P$ . We will illustrate step 2 in toy example. Consider a four-dimensional polytope, where two of the facets are cubes that overlap on a square surface. In figure 26 we show the two facets that overlap along the surface  $\langle abcd \rangle$ .

After triangulating each facet individually, we need to ensure that the triangulations agree on their overlap. Consider triangulations of facet 1 and facet 2, labeled  $\Delta_1$  and  $\Delta_2$ , respectively. If  $\Delta_1$  and  $\Delta_2$  induce the same triangulation on  $\langle abcd \rangle$ , as shown in figure 27, then the pair of triangulations is good, and we store the pair. If instead the triangulations do not agree on the overlap, as in figure 28, we discard the pair.

**Figure 27.** The triangulations  $\Delta_1$  and  $\Delta_2$  agree on the overlap  $\langle abcd \rangle$ .

**Figure 28.** The triangulations  $\Delta_1$  and  $\Delta_2$  do not agree on the overlap  $\langle abcd \rangle$ .

A challenge in the above algorithm is that storing all possible pairs of triangulations at each step becomes costly for  $h^{1,1} \gtrsim 15$ . To access a *subset* of complete, regular, star triangulations in examples with larger  $h^{1,1}$ , one can keep only a subset of the possible pairs at each step, in the following way.

1. Start with two overlapping facets  $F_a$  and  $F_b$ , and determine all regular triangulations of each. Of the regular triangulations of each facet that agree on the overlap, retain the first  $j_1$  pairs, for some number  $j_1$ .
2. Form the intermediate polytope  $F_{ab}$ .
3. Select another overlapping facet  $F_c$ , and compute all regular triangulations of  $F_c$ . Compare each of these to the  $j$  triangulations of  $F_{ab}$ , retaining the first  $j_2$  triangulations of  $F_c$  that agree with a triangulation of  $F_{ab}$  on the overlap of  $F_{ab}$  with  $F_c$ , and that are regular.
4. Repeat steps 2 and 3, adding in facets, until one has obtained one or more triangulations of the full polytope.

Since one only keeps  $j_k$  pairs at step  $k$ , this second method is not guaranteed to yield a triangulation of the full polytope: one can obtain pairs early on for which there is no regular completion of the triangulation. Even so, this method is much faster than the available alternatives, particularly if the  $j_k$  are chosen to be small. We have used this

approach to obtain complete, regular, star triangulations of polytopes with  $h^{1,1}$  as large as 25 on a desktop computer. For  $h^{1,1} \gtrsim 25$  even triangulating the individual facets becomes expensive, and more sophisticated tools are required to obtain triangulations.

We note that our method of triangulation is most successful with polytopes that have many facets. In typical cases, the more facets there are, the fewer triangulations each facet admits, so that the time to triangulate each individual facet is decreased. This gives the algorithm more opportunities to fail at each step, but since the method is fast once all of the facet triangulations are found, we nevertheless find the greatest success for many-faceted polytopes.

After a triangulation is found the resulting fan can be provided as input to **Sage**, which then constructs the corresponding toric variety data, including the intersection ring and Mori cone generators of the ambient toric space. The intersection ring can then be pulled back to the Calabi-Yau hypersurface.
